Experimental studies of new materials demonstrated that the efficiency of solar panels can be increased to 25-28%, which is 2-3% higher compared to conventional silicon modules [5], (Table 7). The integration of perovskite materials and nanotechnologies contributes to both lower production costs and higher efficiency, thereby improving large-scale deployment potential.

Table 7: Comparison of solar panels by efficiency and cost [5], [1].

Panel Type	Efficiency (%)	Cost ($/W)	Service Life (years)	Source
Silicon	20-22	0.3	25-30	[5]
Perovskite	22-25	0.2	15-20	[5], [1]]

These advancements open new opportunities for scaling solar energy and reducing the cost of electricity generation.

4.4 Forecasting Models and Development Scenarios

Technological advancements not only increase energy efficiency but also help address environmental challenges by reducing greenhouse gas emissions.

Tables 8 and 9 summarize fossil resource depletion forecasts, key trends, and observed indicators from 2010–2024, alongside projections to 2030 and 2040. The summary highlights:

- Solar and wind energy – accelerated growth supported by cost reductions, new materials, and technological improvements.
- Hydropower – stable but limited by environmental and geographic constraints.

Table 8: Comparison of fossil resource depletion forecasts [4], [5].

Resource	Current Global Reserves	Annual Consumption	Expected Depletion Time	Forecast Source
Oil	1.7 trillion barrels	4.2 billion barrels/year	~40 years	[7], [8]
Natural Gas	200 trillion m³	3.3 trillion m³/year	~60 years	[7], [8]
Coal	1.1 trillion tonnes	7.8 billion tonnes/year	~140 years	[8]
Uranium (conventional)	6.1 million tonnes	63,000 tonnes/year	~95 years	IAEA, 2023
Unconventional fossil resources	~3.5 trillion barrels (oil equivalent)	varies	~100-150 years	BP Outlook, 2023

Table 9: Summary of key trends and findings.

№	Trend / Indicator	2010-2024 Observation	Forecast to 2030 / 2040	Key Drivers	Source
1	Solar Energy Growth	40 GW → 1700 GW (+20% yillik o‘sish)	2030: 3000 GW	Cost reduction, new materials	[5], Model
2	Wind Energy Expansion	Xitoy & AQSh yetakchi: 200-150 GW	Barqaror +5-8% yillik o‘sish	Turbina innovatsiyalari, subsidiyalar	[4], [9]
3	Hydropower Stability	3000 → 5400 TWh (barqaror)	Cheklangan o‘sish	Ekologik cheklovlar, geografiya	[4], [9]
4	Fossil Fuel Depletion	Neft 1.7 trln bbl → 40 yil qoldi	2040+: tanqislik kuchayadi	Yoqilg‘iga talab, siyosat	[7], [8]
5	CO_2 Reduction via Technologies	25-30% kamayish	Yana -40% ga imkon	Yangi PV, shamol turbinalari, storage	[4], [11]
6	Economic Trends	Solar narxi −85% 2010-2024	Qayta tiklanuvchilar arzonlashadi	Mass-proizvodstvo, innovatsiya	[5]
7	Limitations & Risks	Storage past, integratsiya qiyin	Smart grid + AI bilan yumshaydi	Smart grid, AI, storage	[1]

- Fossil fuels – progressive depletion, underscoring the need for renewable alternatives.
- CO_2 reduction technologies – new photovoltaic systems, improved wind turbines, and integrated storage can substantially decrease emissions.
- Economic trends – declining costs of renewables enable large-scale adoption.
- Integration challenges – energy storage and smart grid deployment remain critical for reliable operation.

This overview illustrates the transformation of the global energy landscape, emphasizing the growing role of renewable energy and technological innovation in achieving sustainability by 2030 and 2040.

5 CONCLUSIONS

This study demonstrates that modern forecasting models and technological advancements provide a clear understanding of renewable energy development prospects. Logistic growth models project that global solar capacity could surpass 3,000 GW by 2030, transforming the energy mix and reducing dependence on fossil fuels. If current trends continue, renewables may constitute 50–60% of global energy by mid-century.

Technological innovations, including advanced photovoltaic materials, wind turbine improvements, and energy storage solutions, enhance efficiency, reduce production costs, and facilitate large-scale deployment. Hydropower remains stable but geographically constrained. The depletion of fossil resources underscores the urgent need for transitioning to renewable sources to ensure energy security and economic stability.

Challenges persist, particularly in energy storage, grid integration, and infrastructure modernization. The development of smart grids, digital technologies, and integrated storage systems is essential to ensure stable and reliable energy supply.

Overall, the findings confirm that renewable energy development is both a necessity—driven by resource depletion and environmental concerns—

and an opportunity to reduce the ecological footprint and combat climate change. Achieving global sustainable development goals requires continued investment in research, technological innovation, and international cooperation.

Keywords: Renewable Energy, Investments, Economic Efficiency, Risks, Monte Carlo Simulation, NPV, IRR, Scenario Analysis, Risk Management, Environmental Sustainability.

Abstract: This paper investigates the economic efficiency and payback performance of renewable energy investment projects, with a focus on solar and wind power plants. The study aims to provide a comprehensive assessment of investment viability by integrating profitability evaluation with advanced risk analysis techniques. A unified analytical framework is proposed, combining traditional financial indicators—Net Present Value (NPV), Internal Rate of Return (IRR), and Payback Period—with modern tools such as sensitivity analysis, scenario modeling, and Monte Carlo simulation. The novelty of the research lies in the integration of probabilistic risk assessment methods and scenario-based modeling into a single framework that captures both technological development and market dynamics. The model incorporates key external factors, including energy price volatility, regulatory changes, and technological innovation, to enhance the accuracy of investment evaluation. The results demonstrate that renewable energy projects are economically viable under baseline conditions, with positive NPV, competitive IRR, and acceptable payback periods. However, project performance is highly sensitive to electricity prices, capital costs, and discount rate assumptions. Monte Carlo simulation confirms a high probability of positive returns, while scenario analysis reveals significant variability in outcomes across optimistic, baseline, and pessimistic conditions. The study emphasizes the importance of flexible investment strategies and effective risk management mechanisms, such as long-term power purchase agreements, insurance instruments, and revenue diversification. Overall, the findings confirm that renewable energy projects offer substantial economic potential when supported by robust analytical evaluation and adaptive risk management approaches, contributing to sustainable energy development.

1 INTRODUCTION

In recent decades, sustainable development and the transition to environmentally friendly energy sources have become critical global priorities. In the context of climate change, fossil fuel depletion, and the urgent need to reduce greenhouse gas emissions, renewable energy (RE) plays a key role in ensuring both environmental and economic stability [1]. Many countries are actively investing in solar, wind, hydro, and biomass energy, highlighting the growing importance of this sector for modern energy policy and economic development [2].

Despite these trends, the economic feasibility of renewable energy projects remains a major challenge. Such projects typically require significant upfront investments and are characterized by relatively long payback periods. Therefore, comprehensive assessment methods that combine profitability and risk analysis are essential for informed decision-making by investors and policymakers [3].

Existing studies widely apply traditional financial indicators such as Net Present Value (NPV), Internal Rate of Return (IRR), and Payback Period (PBP). At the same time, recent research emphasizes the importance of incorporating uncertainty through scenario analysis and Monte Carlo simulation [5], [7]–[9]. However, there is still a lack of integrated frameworks that simultaneously account for financial performance, risk factors, technological change, and regulatory dynamics.

The aim of this study is to conduct a comprehensive assessment of the economic efficiency of renewable energy projects, with particular emphasis on investment risks and payback performance. To achieve this, the study develops an integrated analytical model combining classical financial evaluation methods with advanced risk modeling techniques. The proposed approach also incorporates external factors such as energy price volatility, technological innovation, and regulatory changes.

The scientific contribution of the paper lies in the development of a unified framework that integrates profitability analysis with probabilistic risk assessment. The practical significance of the research is related to its applicability in investment decision-making and the formulation of risk management strategies for renewable energy projects.

The remainder of the paper is structured as follows. Section 2 presents the methodological framework, Section 3 discusses the results, Section 4 provides a discussion, and the final section concludes the study.

2 METHODS

2.1 General Framework and Conceptual Basis

To conduct a comprehensive analysis of the investment attractiveness and associated risks of renewable energy (RE) projects, a systemic approach was developed based on the use of modern methods of economic analysis, risk modeling, and profitability evaluation [6]. The research methodology integrates both classical and innovative approaches, enabling the consideration of project-specific technological features, market conditions, and external factors.

The primary goal of these methods is to obtain objective, reproducible, and representative results that enable the comparison of projects in terms of investment appeal and the identification of effective risk mitigation strategies. In accordance with this objective, the methods applied in the study are classified into the following categories:

- Analytical methods (for economic efficiency evaluation);
- Modeling methods (for risk and scenario simulation);
- Statistical methods (for sensitivity and probability analysis);
- Expert-based methods (for qualitative assessment and validation).

2.2 Analytical Methods for Evaluating the Efficiency of Renewable Energy Projects

2.2.1 Net Present Value (NPV) Method

The most widely used indicator for evaluating investment efficiency is the Net Present Value (NPV), which reflects the difference between the present value of cash inflows and the present value of cash outflows over the project's lifecycle. It is calculated using the following formula:

$$NPV = \sum_{t=1}^{n} \frac{C_t}{(1+r)^t} - C_0 \quad (1)$$

Where (1):

- Rt- project revenues in year *t*;
- Ct - project costs in year *t*;
- r - discount rate;
- n - project duration (in years).

A positive NPV indicates that the project is economically viable and capable of generating value above its cost of capital, while a negative NPV suggests financial inefficiency or excessive risk exposure.

This method makes it possible to account for the time value of money and determine how profitable a project is, taking into consideration all future cash flows [6].

2.2.2 Internal Rate of Return (IRR)

The Internal Rate of Return (IRR) is the discount rate at which the Net Present Value (NPV) of a project equals zero. It can be expressed by the following equation:

$$0 = \sum_{t=1}^{n} \frac{C_t}{(1+IRR)^t} - C_0 \quad (2)$$

This indicator makes it possible to determine the project's rate of return and compare it with alternative investment opportunities. If the IRR exceeds the minimum required rate of return (for example, the benchmark rate for comparable projects or the inflation rate), the project is considered financially attractive [11].

2.2.3 Payback Period (PBP)

The Payback Period (PBP) represents the time span required for cumulative net cash inflows to offset the initial investment cost. It is defined as the minimum period (t_t) during which the sum of discounted cash flows becomes equal to or exceeds the initial outlay [3].

These indicators - NPV, IRR, and PBP - provide a preliminary evaluation of project efficiency; however, they do not take into account the influence of risk factors or alternative development scenarios, which are critical in the dynamic renewable energy market.

2.3 Risk and Uncertainty Modeling

To assess the risks associated with renewable energy investments, a combination of scenario modeling, sensitivity analysis, and statistical simulation methods, including Monte Carlo modeling, was employed. These methods make it possible to capture the probabilistic nature of uncertainties that affect the performance and financial viability of renewable energy projects.

2.3.1 Scenario Analysis

Scenario analysis involves constructing three distinct development scenarios-optimistic, baseline, and pessimistic-to estimate the range of possible project outcomes and their probabilities. Within this method, the main variables influencing project efficiency-such as electricity price, equipment cost, and discount rate-are systematically varied to analyze their impact on performance metrics like NPV and IRR [12].

This approach enables decision-makers to visualize potential risks and benefits under changing external conditions and to prepare adaptive investment strategies for each scenario.

2.3.2 Sensitivity Analysis

The sensitivity analysis method involves varying key project parameters within a predefined range and evaluating how these changes affect the project's efficiency indicators. This technique identifies the most sensitive or vulnerable variables, such as capital cost, energy price, or operational expenses, and helps determine priority areas for risk mitigation [13].

By quantifying parameter elasticity, sensitivity analysis supports the design of robust financial models and provides a deeper understanding of which factors most significantly influence the investment outcome.

2.3.3 Monte Carlo Simulation

The Monte Carlo simulation method allows the simultaneous consideration of multiple uncertainties by generating a large number of simulated scenarios based on random parameter distributions. Through iterative computation, the model produces probabilistic estimations of key financial metrics such as NPV and IRR, enabling the determination of the likelihood of achieving specific profitability targets [14].

Figure 1 presents a schematic representation of the Monte Carlo simulation process applied for evaluating renewable energy projects. The procedure includes the following stages:

1) Definition of input variables and their probability distributions;
2) Generation of random values for each variable;
3) Repeated simulation of project outcomes;
4) Construction of output probability distributions for NPV and IRR;
5) Assessment of investment risk and decision-making under uncertainty.

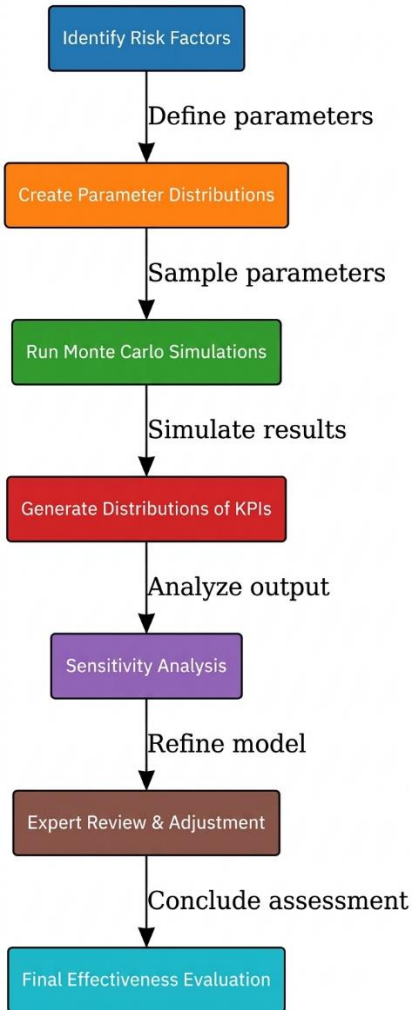

Figure 1: Monte Carlo simulation framework for assessing the efficiency of renewable energy projects.

The block diagram illustrates the structure of the Monte Carlo simulation process applied to evaluate the effectiveness of renewable energy projects. The procedure begins with the identification of risk factors and the construction of probability distributions for key parameters. Iterative computations are then performed, generating distributions of key performance indicators (KPIs) such as NPV and IRR, followed by a sensitivity analysis of the results. This stage makes it possible to determine which parameters exert the greatest influence on the simulation outcome.

The subsequent step involves expert validation and model adjustment, after which the final assessment of project efficiency is produced. Such visualization is particularly useful for representing complex analytical processes in a simplified and logically consistent form. The block diagram enhances the understanding of the simulation structure and is widely applicable in both technical reports and educational materials.

2.4 Statistical Methods for Risk Assessment

Statistical analysis in this study employs methods such as regression analysis, correlation analysis, and confidence interval estimation to evaluate the relationship between project efficiency indicators and external factors. These methods make it possible to identify the main risk drivers and quantify their influence on project outcomes.

2.4.1 Regression Analysis

Regression analysis is used to determine the relationship between project performance and influential variables such as electricity price, technological costs, and the level of government support. The analysis utilizes a multiple regression model, expressed as follows:

$$Y=\beta_0+\beta_1X_1+\beta_2X_2+\cdots+\beta_kX_k+\varepsilon \quad (3)$$

Where (3):

- Y - dependent variable representing the project efficiency indicator (e.g., NPV, IRR);,
- X_i - independent variables representing risk factors (e.g., energy price, investment cost, regulatory stability);
- β_i - regression coefficients;
- ε - random error term.

The results of the regression analysis help determine the significance of key factors and enable the prioritization of risk management measures [15].

2.4.2 Confidence Interval Estimation

This method provides an assessment of the range within which the true value of project efficiency indicators lies with a given probability level. Standard statistical techniques are used, such as the Wald method or bootstrap estimation, which allow for robust evaluation of parameter uncertainty and variability [16].

Confidence interval estimation helps quantify the statistical reliability of NPV, IRR, and other financial metrics under varying market conditions, providing a more transparent foundation for investment decision-making.

2.5 Expert-Based Risk Assessment Methods

In cases where statistical data are insufficient or unavailable, expert judgment methods are applied. These rely on structured interviews, group discussions, and the Delphi method to collect and consolidate the opinions of qualified specialists regarding different aspects of renewable energy projects.

The collected assessments are subsequently aggregated and analyzed to estimate the probability of risk occurrence and the extent of its potential impact [17]. This approach complements quantitative techniques by incorporating experiential and contextual knowledge, thereby enhancing the robustness of the overall risk evaluation framework.

2.6 Development of an Integrated Model for Investment Attractiveness Assessment

Based on the methods described above, an integrated model for assessing the efficiency and risks of renewable energy projects was developed. The model is grounded in a multifactor structure that combines indicators such as NPV, IRR, payback period, and probabilistic risk evaluations.

The model includes the following stages:

1) Risk factor identification - collection of data on external and internal variables affecting project performance;
2) Scenario modeling - development of value ranges for key project parameters;
3) Monte Carlo simulation - generation of probabilistic distributions for efficiency indicators;
4) Sensitivity analysis - identification of the most vulnerable project components;

5) Expert evaluation - refinement of simulation results based on expert insights;
6) Result synthesis - integration of findings and formulation of final indicators and recommendations.

This integrated approach ensures both quantitative precision and qualitative validation, providing a comprehensive tool for investment decision-making in the renewable energy sector.

2.7 Integration of Technical and Economic Aspects into the Analytical Framework

To improve the accuracy and realism of the assessment, the model incorporates both technical and economic parameters, reflecting the actual operational and technological state of the project [3]. Specifically, the model includes indicators such as:

- Capacity utilization factor**;**
- Degree of technological wear and obsolescence**;**
- Dynamics of component and raw material prices**;**
- Level of governmental and institutional support**.**

The inclusion of these parameters ensures that the model captures the technological maturity, economic dynamics, and policy environment, thereby enhancing the robustness of investment analysis.

2.8 Methodological Interrelation and Sequential Application

To ensure the reliability and consistency of the research findings, a structured methodological sequence was adopted, enabling a comprehensive and multi-layered project evaluation:

1) Analytical efficiency assessment - preliminary evaluation of NPV, IRR, and payback period;
2) Sensitivity and scenario analysis - assessment of project resilience to parameter changes;
3) Monte Carlo simulation - derivation of probabilistic characteristics and confidence distributions;
4) Statistical analysis - identification of key risk drivers through regression and correlation methods;
5) Expert evaluation - incorporation of qualitative insights to complement quantitative findings and address uncertainty.

This sequential approach allows for a systematic evaluation of renewable energy projects, balancing quantitative modeling with expert-driven interpretation, and serves as the foundation for the development of an evidence-based decision-support framework for sustainable investments (Table 1).

Table 1: Sequence of methods for evaluating the efficiency and risks of renewable energy projects.

Stage	Methods	Purpose	Outcome
1	NPV, IRR, Payback Period	Preliminary efficiency assessment	Baseline project indicators
2	Scenario Analysis, Sensitivity Analysis	Evaluation of project resilience	Range of performance indicators
3	Monte Carlo Simulation	Probabilistic assessment	Probability distributions of NPV and IRR
4	Regression Analysis, Confidence Intervals	Analysis of factor influence	Identification of key risk drivers
5	Expert Evaluation	Consideration of uncertainties	Final integrated risk assessments

3 RESULTS

This section presents the results of the economic efficiency and risk assessment of renewable energy investment projects based on scenario modeling and probabilistic analysis.

The findings include an evaluation of investment attractiveness, identification of key risk factors, and a comparative analysis of different project types. The results also support the development of strategies for risk mitigation under varying market and regulatory conditions.

3.1 The Discounted Cash Flow (NPV) Method of Financial Efficiency Analysis of Projects

According to the discounted cash flow (DCF) analysis, both solar and wind power projects are economically viable. Under the baseline scenario, assuming a 20-year project lifetime, an 8% discount rate, and annual cash flows of USD 6.5–9.2 million, the estimated NPV amounts to USD 35.4 million, with an IRR of 11.5% and a payback period of approximately 6.2 years.

Two project types were analyzed for comparative purposes: solar power plants (SPP) and wind power plants (WPP). The main parameters and evaluation results are summarized in Table 2.

Table 2: NPV evaluation results for renewable energy projects.

Parameter	Value	Measurement Unit	Notes / Description
Initial Investment	50	million USD	Construction + equipment
Project Lifetime	20	years	-
Discount Rate	8	%	Industry average
Annual Cash Flows	6.5 - 9.2	million USD/year	By scenario
NPV, baseline scenario	35.4	million USD	-
IRR	11.5	%	Internal rate of return
Payback Period	6.2	years	-

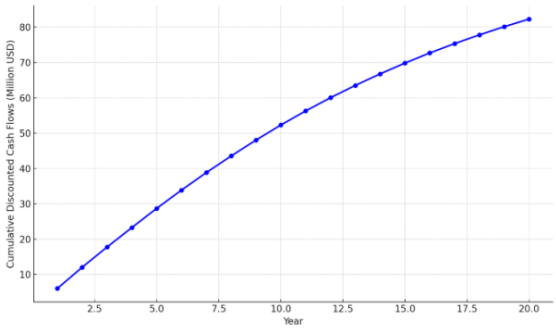

Figure 2: Cumulative discounted cash flow curve for the renewable energy project.

Figure 2 shows the cumulative discounted cash flow over the project lifecycle. The results indicate that the break-even point is reached around year 6, after which the project generates stable positive returns. The upward trend of cumulative discounted cash flows confirms the financial sustainability of the project under the assumed conditions.

Overall, both project types demonstrate positive financial performance, with key indicators exceeding minimum investment requirements. However, their long-term profitability remains sensitive to external market and regulatory factors.

3.2 Sensitivity Analysis and Scenario Evaluation

Sensitivity analysis shows that the most sensitive parameters for NPV are electricity price and equipment cost. A ±20% of electricity price leads to an ±USD 8.5 million variation in NPV, and also for equipment cost, there is a change of ±USD 5.2 million.

The sensitivity of profitability to the scenario (optimistic, baseline, and pessimistic) also shows that profit is very sensitive to market conditions. Efficiency measures improve dramatically in the best-case scenario, but returns decrease and risks increase in the other scenarios. These results support the value of hedging instruments and long-term contracts.

Table 3 presents the results of the sensitivity assessment for key financial and external factors, showing how variations in these parameters affect project performance metrics such as NPV and IRR.

These results confirm that the most sensitive parameters are the electricity price and equipment cost. Therefore, to enhance the project's financial resilience, it is recommended to employ long-term power purchase agreements (PPAs) and optimize procurement strategies for technological components. Such measures help stabilize cash flows, mitigate exposure to market volatility, and improve overall investment predictability.

Table 3: Results of NPV sensitivity analysis.

Factor	Range of Variation	Impact on NPV	Measurement Unit	Conclu-sion
Electri-city price	±20%	±8.5	million USD	Most sensitive
Equip-ment cost	±15%	±5.2	million USD	High impact
Interest rate	±2%	±4.1	million USD	Important finance factor
Opera-tional lifetime	±2	±3.8	years → million USD	Affects long-term returns

Figure 3 illustrates the relationship between Net Present Value (NPV) and electricity price for the analyzed renewable energy project. The results show that NPV is highly sensitive to market price

fluctuations: a decrease below approximately 60 USD/MWh leads to negative project returns, while increasing prices (from 40 to 80 USD/MWh) result in a steady growth of NPV. This demonstrates the critical importance of stable pricing mechanisms and highlights the need for hedging strategies and revenue diversification. The analysis also allows identification of the break-even threshold, supporting investment decision-making under market uncertainty.

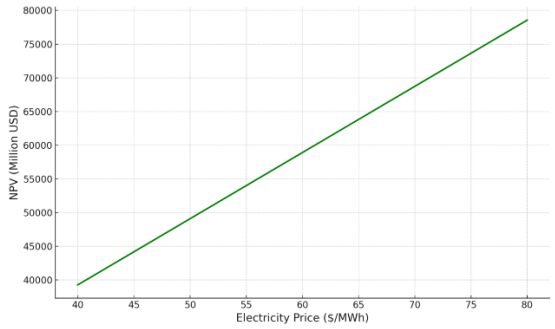

Figure 3: Relationship between NPV and electricity price.

3.3 Risk Modeling Using the Monte Carlo Method

To obtain a more accurate probabilistic evaluation of project efficiency, a Monte Carlo simulation model was applied. The input parameters included probability distributions for equipment cost, electricity price, discount rate, and other key variables.

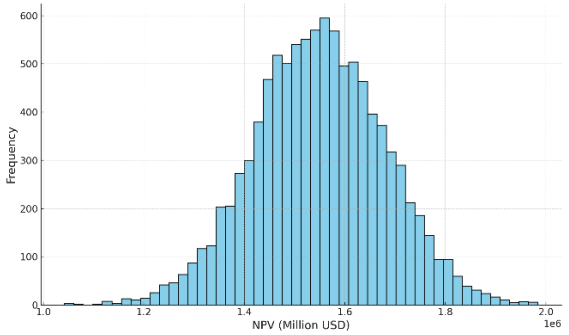

Figure 4: NPV distribution histogram for the wind power project (Monte Carlo simulation).

Figure 4 presents the distribution of Net Present Value (NPV) for the wind power project based on 10,000 simulation iterations. The results indicate a mean NPV of 34.8 million USD with a standard deviation of 4.5 million USD. The probability of negative NPV is below 5%, while the likelihood of achieving payback exceeds 80% under baseline conditions.

These findings confirm the robustness of the project and its high probability of generating positive returns despite underlying uncertainties.

3.4 Influence of External Factors and Risks

The analysis of external factors, including tariff policies, technological innovation, and political stability, revealed several important findings. The introduction of tariff incentives or subsidies can increase project NPV by 15–20%, while political instability and regulatory changes may raise overall project risk by up to 30%. At the same time, technological innovations can reduce capital expenditures by 10–12%, improving both payback period and return on investment.

Figure 5 shows the relative impact of key risk factors on project efficiency. Electricity price fluctuations have the strongest influence (25%), followed by technological risks (20%) and regulatory changes (15%), while other factors such as political stability and market conditions have a moderate effect.

These results highlight the critical importance of managing price volatility and regulatory risks to ensure project stability and investment attractiveness.

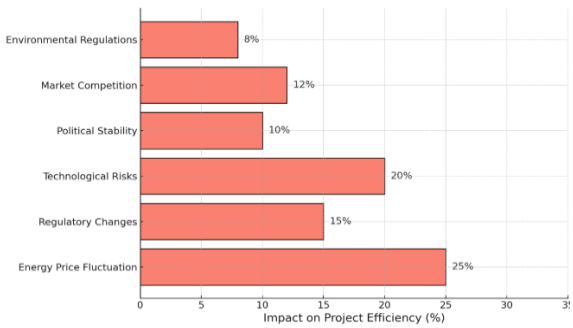

Figure 5: Impact of risk factors on the efficiency of a renewable energy project.

3.5 Comparison of Different Implementation Scenarios

As part of the study, three development scenarios were analyzed: optimistic, baseline, and pessimistic. Table 4 summarizes the key performance indicators (KPIs) for each scenario, providing a comparative overview of project outcomes under varying market and policy conditions.

This analysis shows that under the optimistic scenario, the project's efficiency increases significantly; however, under the pessimistic scenario, the level of risk rises substantially, necessitating the implementation of additional risk management measures.

Table 4: Comparison of scenarios for the wind power project.

Parameter	Optimistic Scenario	Baseline Scenario	Pessimistic Scenario	Measurement Unit
NPV	45.7	34.8	22.3	million USD
IRR	14.8	11.5	8.2	%
Payback Period	5.4	6.2	8.1	years
Probability of positive NPV	95	85	65	%

3.6 Summary and Key Findings

Summarizing the obtained results, the following conclusions can be drawn:

- Renewable energy projects demonstrate high investment attractiveness when evaluated using modern methods such as discounted cash flow analysis and Monte Carlo simulation;
- The most sensitive parameters to external influences are the electricity price and equipment cost, which have the greatest impact on NPV and IRR;
- Scenario variability indicates that, with proper strategic and operational management, the risk of negative returns can be minimized to negligible levels;
- External factors, including regulatory changes and technological innovations, significantly affect payback periods and profitability, highlighting the need for continuous monitoring and adaptive investment strategies.

These findings confirm that the combination of quantitative modeling, scenario analysis, and expert-based evaluation provides a robust foundation for decision-making in the renewable energy sector, enabling investors to balance profitability and risk under uncertain market conditions.

3.7 Visualization of Results

Figure 6 presents a summary chart illustrating the NPV distribution across three project scenarios-optimistic, baseline, and pessimistic. The visualization highlights the shifts in expected value and probability range, allowing for a clear comparison of financial outcomes and risk exposure under different development conditions.

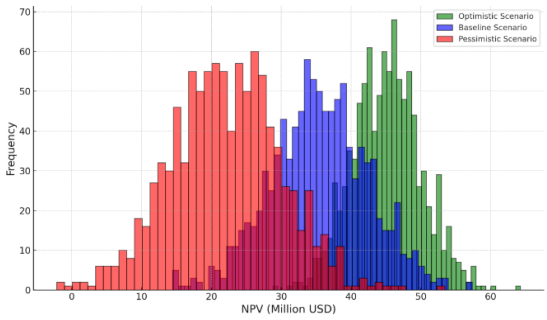

Figure 6: Distribution of NPV across different project implementation scenarios.

Such graphical representation serves as an effective tool for strategic communication with stakeholders, as it visually conveys both the expected profitability and the uncertainty margins associated with each scenario.

The histogram illustrates the distribution of the Net Present Value (NPV) of a renewable energy investment project under three scenarios: optimistic, baseline, and pessimistic. Each scenario models possible financial outcomes based on a normal probability distribution with distinct mean values and standard deviations.

- The green curve represents the optimistic scenario, characterized by the highest expected returns;
- The blue curve corresponds to the baseline case;
- The red curve denotes the pessimistic scenario, reflecting the least favorable market and policy conditions.

The frequency of values provides insight into the likelihood of achieving specific profitability levels. This comparative approach enables a comprehensive assessment of uncertainty and risk, highlighting the potential variability of financial outcomes. The

absence of a title within the figure enhances its flexibility for integration into various analytical or policy reports.

Such visualization serves as an essential tool for investors and analysts, facilitating the evaluation of probabilistic performance metrics and supporting data-driven investment decisions in the renewable energy sector.

4 DISCUSSION

This section provides an interpretation of the obtained results, comparing them with the findings of other researchers and discussing the key factors affecting the efficiency and risk profile of renewable energy (RE) projects. The discussion synthesizes the insights derived from the applied analytical framework, including investment efficiency assessment, scenario modeling, sensitivity analysis, and Monte Carlo simulations.

The discussion not only contextualizes the results within the broader scientific discourse but also forms the basis for practical recommendations and identifies directions for further research in renewable energy investment evaluation.

4.1 Comparative Analysis with International Experience

The findings are consistent with international studies emphasizing the importance of scenario-based analysis and risk-adjusted profitability measures. The analyzed renewable energy projects demonstrate high profitability under baseline conditions and strong sensitivity to market uncertainties.

A comparison of NPV across scenarios shows that optimistic assumptions significantly improve financial outcomes, whereas pessimistic conditions highlight sensitivity to electricity price volatility and regulatory risks. These results confirm the importance of probabilistic methods, such as Monte Carlo simulation, in investment decision-making.

Figure 7 shows the comparison of NPV values under three scenarios. The optimistic scenario yields the highest NPV (USD 45.7 million), followed by the baseline case (USD 34.8 million), while the pessimistic scenario results in the lowest value (USD 22.3 million).

These results highlight the impact of external conditions on project profitability and emphasize the need for effective risk management strategies.

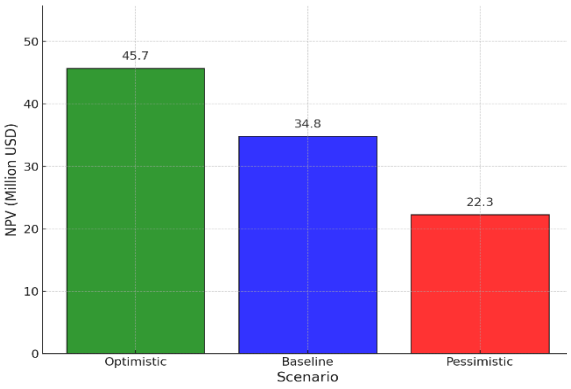

Figure 7: Comparison of NPV under different project implementation scenarios.

4.2 Impact of Key Risk Factors on Project Efficiency Indicators

The sensitivity analysis revealed that the most influential parameters affecting NPV and IRR include electricity price fluctuations, equipment costs, discount rate, and project lifespan [13], [15]. As demonstrated in Table 3, a ±20% change in the electricity price results in an approximate ±USD 8.5 million variation in NPV, confirming the project's high sensitivity to market price volatility.

Figure 8 illustrates the relative impact of major risk factors on project performance. Notably, changes in electricity price and equipment costs produce the largest deviations in NPV and IRR, aligning with the findings of Study [18], which emphasizes the necessity of long-term power purchase agreements (PPAs) and income stream diversification to mitigate financial risks.

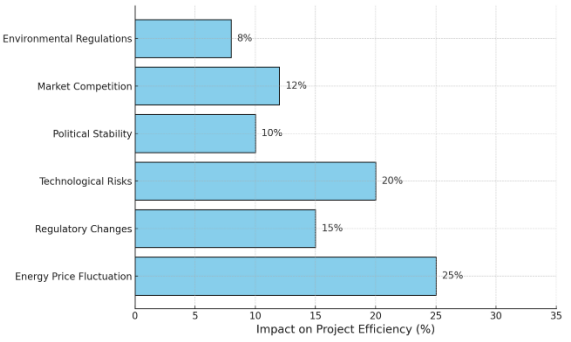

Figure 8: Impact of risk factors on project efficiency indicators.

This horizontal bar chart presents the key risks influencing the effectiveness of renewable energy project implementation. Each bar indicates the magnitude of impact of a specific factor, expressed as a percentage.

The most critical risk is associated with electricity price fluctuations (25%), followed by technological risks (20%) and regulatory changes (15%). Other factors-such as political stability, market competition, and environmental regulations-exert a moderate yet significant influence on project outcomes.

The absence of an internal title makes the figure versatile and easily adaptable for integration into reports, presentations, and technical documents. The values are labeled directly on the bars, allowing for immediate data interpretation without additional legends.

This visualization is particularly effective for identifying project vulnerabilities and developing targeted risk mitigation strategies. The results emphasize the necessity of implementing hedging mechanisms, long-term planning, and diversified financial instruments to reduce project exposure to external market volatility.

4.3 Monte Carlo Risk Modeling: Interpretation and Conclusions

The Monte Carlo simulation model was applied to evaluate the probability distribution of NPV for the project. The results indicate that the likelihood of a negative NPV is below 5%, suggesting a high probability of successful project implementation. The histogram in Figure 9 shows that most simulated scenarios yield positive NPV values, with a distribution centered near the mean (USD 35 million) and a standard deviation of USD 5 million, reflecting potential variability in project outcomes.

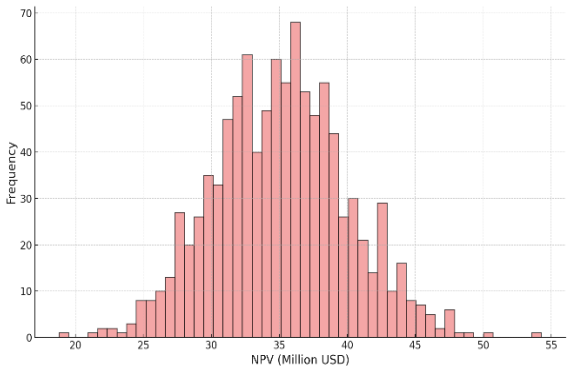

Figure 9: Distribution of NPV from Monte Carlo simulation results.

These findings are consistent with previous research [14], highlighting the effectiveness of Monte Carlo simulations in assessing investment risk and uncertainty in the energy sector. The analysis of IRR further confirms that its mean value exceeds the minimum acceptable threshold, reaffirming the project's investment appeal. Overall, probabilistic evaluation provides a quantitative foundation for risk-informed decision-making and strategic capital allocation.

4.4 Influence of External and Regulatory Factors

The analysis of external factors revealed that changes in tariff policy, regulatory requirements, and political instability can significantly affect project performance indicators [5], [14]. As shown in Table 5, under favorable conditions, project NPV can increase by 20-25%, while under unfavorable conditions it may decrease by 30% or more.

Figure 10 presents the sensitivity of NPV to these external factors. Electricity price fluctuations have the strongest impact (25%), followed by technological changes (20%) and regulatory adjustments (15%). Other factors, including political stability, market competition, and environmental regulations, exert a moderate effect on project outcomes.

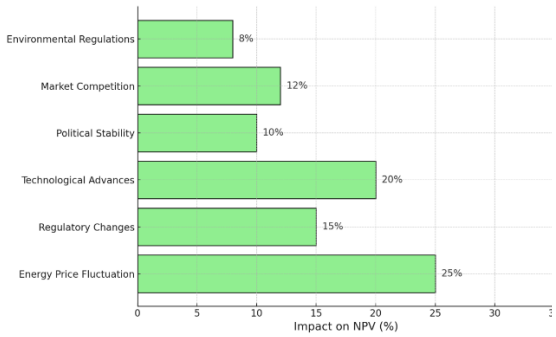

Figure 10: Sensitivity of NPV to external factors affecting renewable energy projects..

These findings highlight the importance of regulatory predictability, policy stability, and institutional support for the economic resilience of renewable energy projects. To mitigate external risks, strengthening policy frameworks, enhancing investment guarantees, and promoting collaborative governance mechanisms between public and private sectors are recommended. Additionally, monitoring technological innovation and integrating adaptive

business models are essential to maintain competitiveness and investment stability.

4.5 Practical Recommendations and Directions for Further Research

Based on the analysis, the following practical recommendations are proposed for investors and project managers in the renewable energy sector:

- Implement insurance and hedging mechanisms to mitigate risks associated with price volatility and regulatory changes.
- Apply scenario analysis and Monte Carlo simulations to assess probabilistic project performance.
- Develop long-term power purchase agreements (PPAs) and diversify revenue streams to reduce dependency on single market factors.
- Engage proactively with regulatory authorities to support stable tariff policies and encourage technological innovation.
- Monitor emerging technologies continuously and ensure adaptive investment management.

For future research, it is recommended to:

- Analyze the impacts of climate change and environmental regulations on project performance.
- Develop risk assessment models incorporating next-generation technologies, such as energy storage systems and smart grid infrastructure.
- Expand region-specific studies to capture policy, market, and technological variations.

4.6 Limitations and Prospects for Future Development

Despite the comprehensiveness of the applied methods, limitations include the reliance on input data quality and assumptions about probability distributions. The absence of long-term data for emerging technologies may reduce the precision of projections.

Potential improvements:

- Integrate dynamic system models for renewable energy markets.
- Utilize machine learning for enhanced market forecasting.
- Expand geographic and policy-specific analyses to improve predictive accuracy.

Overall, integrating risk assessment, scenario-based analysis, and probabilistic modeling enhances decision-making reliability and supports resilient investment strategies.

5 CONCLUSIONS

This study assessed the economic efficiency and investment risks of renewable energy projects, focusing on solar and wind power plants. Key findings include:

- Renewable energy projects demonstrate strong potential for positive economic returns, subject to external factors such as electricity prices, regulatory policies, and technological developments.
- Scenario analysis and Monte Carlo simulations provide robust probabilistic insights, supporting informed investment decisions under uncertainty.
- The main risk drivers are energy price volatility, regulatory changes, and technological uncertainty. Mitigation strategies include long-term contracts, risk management instruments, and adaptive investment practices.

In conclusion, renewable energy projects are economically viable and strategically sound when accompanied by effective risk management and continuous monitoring of market and technological conditions.

Keywords: Renewable Energy, Solar Power, Wind Energy, Investment, Environmental Security, Energy Policy, Uzbekistan, Sustainable Development, Green Energy.

Abstract: This article presents an analytical review of the development of the renewable energy sector in Uzbekistan during the period 2021-2025. The study includes an assessment of investment dynamics, renewable electricity generation, and the implementation of large-scale solar and wind power projects, along with an analysis of the regulatory framework and state support mechanisms. The results reveal a significant increase in investment and clean energy production, contributing to the reduction of environmental impacts, creation of new jobs, and strengthening of the country's energy security. A comparative analysis with international practices is conducted, identifying both internal and external barriers to sectoral development and proposing policy recommendations aimed at improving the effectiveness of government support, infrastructure expansion, and the integration of innovative technologies. The article also explores the social and environmental implications of renewable energy deployment and outlines the growth prospects of the sector up to 2030. The scientific analysis indicates that further development requires enhanced state support through the establishment of long-term tariff mechanisms, expansion of financial instruments (e.g., green bonds, joint financing funds), and the adoption of energy storage innovations and digital management systems. Furthermore, international cooperation and knowledge exchange are identified as key drivers for accelerating progress. The findings confirm Uzbekistan's high potential in the field of green energy and emphasize the necessity of systemic reforms to achieve strategic objectives for sustainable development and climate neutrality. The outcomes of this research can serve as a scientific and policy foundation for national energy programs, academic studies, and investment strategies in the renewable energy domain.

1 INTRODUCTION

In recent decades, sustainable development and energy security have become critical issues worldwide. Rapid economic growth has led to increasing energy consumption, while traditional resources such as oil, gas, and coal face limitations due to depletion and environmental impacts. Renewable energy sources (RES) have emerged as a key component of global strategies to ensure a reliable and environmentally sustainable energy supply [1], [2]. The deployment of RES contributes not only to reducing greenhouse gas emissions but also to fostering technological innovation and decreasing dependence on imported fuels. In this context, government policies play a crucial role by establishing regulatory frameworks and adopting supportive measures that facilitate the development and expansion of the renewable energy sector [2], [13].

Global initiatives, such as the 2015 Paris Agreement, set clear targets for reducing greenhouse gas emissions and transitioning to a low-carbon economy [3]. Signatory countries are required to develop national renewable energy action plans and fulfill their international commitments, highlighting the increasing importance of well-structured national programs. International organizations, including the International Energy Agency (IEA) and the World

Bank, actively support renewable energy initiatives through financial instruments and technical expertise [1], [4], while national legal systems provide the foundation for strategies, standards, and regulations that guide the sector's development.

Uzbekistan possesses significant potential for renewable energy due to favorable climatic conditions, abundant natural resources, and strategic geographic location [5]. Despite this potential, renewable energy penetration in the country remains relatively low compared with leading global economies, largely as a result of limited regulatory frameworks, insufficient state support, and challenges in project implementation [5], [11]. In recent years, the government has shown growing interest in solar, wind, and hydropower projects, yet large-scale deployment requires a comprehensive national strategy that includes incentive mechanisms, regulatory reform, and expansion of infrastructure and technological capacity.

This study aims to analyze the current state of government policy and regulatory frameworks for renewable energy deployment in Uzbekistan and to propose effective policy instruments to accelerate sectoral development based on international best practices and empirical analysis. The research examines international standards and policy approaches, evaluates the existing legal environment in Uzbekistan, identifies key barriers and drivers of renewable energy deployment, and develops targeted recommendations to improve policy and support mechanisms. Furthermore, a conceptual model for designing effective policy tools is presented to guide sustainable growth in the sector [4], [13].

The methodology combines system analysis, comparative legal review, expert assessment, and modeling techniques, drawing on official government documents, academic literature, reports from international organizations, and national statistical data [4], [13]. The findings of this study are expected to inform the development of new policy strategies, regulatory measures, and state support mechanisms that promote renewable energy growth, strengthen energy independence, improve environmental sustainability, and enhance investment attractiveness. Future research should focus on evaluating the effectiveness of implemented policies, developing simulation and modeling tools, and assessing the socio-economic impacts of renewable energy deployment, with particular attention to intersectoral collaboration between government bodies, private enterprises, and the academic community to support Uzbekistan's transition toward a sustainable energy future.

2 RESEARCH METHODS

2.1 General Characteristics of the Research Methodology

Achieving the stated research objectives requires a comprehensive approach that combines methods of system analysis**,** comparative legal research**,** expert evaluation**,** and modeling [14], [16]. This approach enables a multidimensional assessment of the regulatory landscape, identification of key challenges**,** and formulation of evidence-based recommendations**.**

The study employs an interdisciplinary perspective**,** integrating legal, economic, technological, and policy dimensions. Such a combination enhances the accuracy, robustness, and scientific validity of the findings while ensuring a holistic understanding of renewable energy governance processes.

2.2 Data Collection and Analytical Methods

To obtain reliable insights into the current status of Uzbekistan's regulatory framework and renewable energy policy, the following methods were applied:

- Document analysis - examination of legal acts, strategic programs, international reports, analytical materials, academic studies, and official statistics [4], [13], [17];
- Qualitative analysis - identification of trends, barriers, and incentives through expert interviews and content analysis of policy documents;
- Quantitative analysis - statistical evaluation of renewable energy deployment, investment trends, and policy effectiveness indicators.

These combined methods provide a comprehensive understanding of the policy environment and reveal causal relationships between governance structures, financial instruments, and technological progress [14], [16].

2.3 Application of System Analysis Methods

System analysis serves as a core methodological tool for evaluating the complex, multifactor processes governing renewable energy development and regulatory evolution [15]. This method allows researchers to model interdependencies, identify feedback mechanisms, and design strategies for optimization.

Key stages of the system analysis include:

- Identification of system components - describing actors, institutions, policies, economic mechanisms, technologies, and infrastructure elements shaping renewable energy development;
- Modeling interrelationships - constructing diagrams, matrices, and causal networks illustrating how legal and policy changes affect sectoral growth;
- Sensitivity and scenario analysis - assessing the system's response to different policy interventions and legislative reforms.

A sample structural model of the system is illustrated in Figure 1.

The diagram illustrates a systemic model of renewable energy governance in Uzbekistan. The visualization is presented as a directed network, where each node represents a key element or process influencing renewable energy deployment - legislation, investment support, infrastructure, technological development, markets, and renewable energy growth. The arrows between nodes indicate causal relationships and interactions among these components (Table 1).

For example, legislative initiatives directly facilitate both investment support and the expansion of the renewable energy sector. Investment incentives influence infrastructure development and simultaneously stimulate renewable energy deployment, which in turn contributes to the expansion of energy markets. Technological advancement has a bidirectional effect - it enhances infrastructure quality and directly supports renewable energy growth.

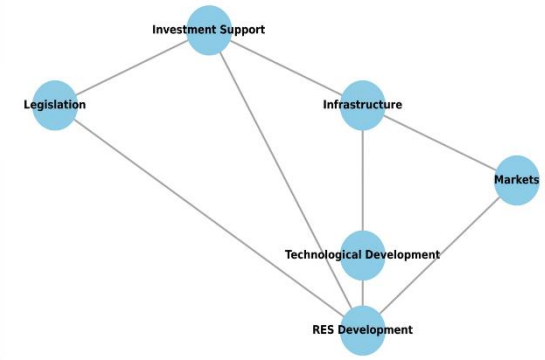

Figure 1: Growth in electricity generation from renewable energy sources (2021-2025).

This model highlights the interconnectedness of political, technical, and market mechanisms that are essential for ensuring the sustainable development of renewable energy in the country. The presented framework serves as a basis for further quantitative and qualitative assessments of the effectiveness of existing and proposed policy mechanisms.

2.4 Comparative Analysis Methods

The comparative analysis was conducted through a systematic review of international practices and regulatory frameworks in leading renewable energy countries such as Germany, China, the United States, and European Union (EU) member states [10], [11], [16].

Table 1: Investment Volume in the Renewable Energy sector (2021-2025).

Country	Key Support Instruments	Level of Government Support	Renewable Energy Development Effectiveness	Regulatory Framework Characteristics
Germany	Renewable Energy Act (EEG), Feed-in Tariffs	High	High	Developed infrastructure, long-term tariff stability
China	State programs, subsidies, tax incentives	Very High	Very High	Promotion of domestic technology production
United States	Market mechanisms, tax credits	Moderate	High	Regional diversity, incentive-driven policies
European Union	Common directives, national programs	High	Medium	Harmonized regulations, market integration

This approach enables the identification of best practices, their adaptation to Uzbekistan's national context, and the determination of potential areas for policy improvement.
The comparative analysis employed the following tools:

- Evaluation criteria - encompassing levels of government support, incentive mechanisms, regulatory instruments, financial measures, infrastructure projects, and market regulation systems.
- Cross-tabulation method - used to structure and compare differences and similarities across national regulatory models.
- Qualitative and quantitative assessment - to evaluate policy efficiency, sustainability, and scalability of renewable energy development across different countries.

The detailed comparison reveals the key success factors and potential risks associated with adapting international regulatory practices to the Uzbekistan energy context**.** Findings from this cross-national analysis form the analytical foundation for policy optimization and institutional reform proposals.

2.5 Expert Evaluation Methods

To assess the effectiveness of the current regulatory framework and determine priority areas for renewable energy development, expert evaluation methods were applied - including structured surveys and semi-structured interviews. Experts were selected from academic institutions, government agencies, business enterprises, and industry associations.
The procedure included:

- Design of a structured questionnaire, focusing on the state of the legal framework, existing barriers, incentive mechanisms, and development prospects of the renewable energy sector;
- Personal and online interviews, enabling the collection of in-depth qualitative data and identification of expert opinions on key challenges;
- Processing and statistical analysis of responses using techniques such as mean value estimation, consistency assessment, and error analysis.

The results of expert evaluations were utilized to validate or refute the working hypotheses and to develop evidence-based recommendations for improving public policy and support mechanisms [17].

2.6 Modeling and Scenario Development

To evaluate the potential trajectories of renewable energy sector growth and the efficiency of proposed policy instruments, the study employed system dynamics modeling. This method facilitated the development of multiple scenarios of sectoral evolution, reflecting variations in policy frameworks, investment levels, technological progress, and macroeconomic conditions.

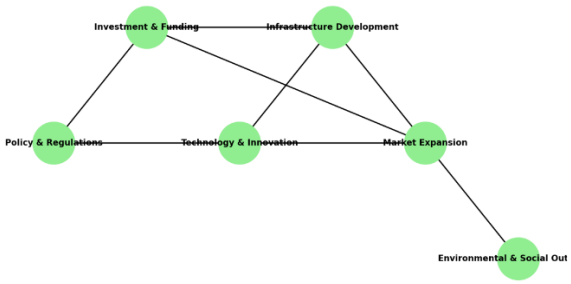

Figure 2: Infrastructure bottlenecks and their impact on development.

The modeling approach enables:

- Forecasting of renewable energy generation growth under different policy regimes;
- Assessment of investment return and market elasticity in response to incentive measures;
- Sensitivity analysis to determine the most influential policy and economic factors driving sectoral change.

The resulting models provide a quantitative foundation for strategic planning and serve as a decision-support tool for policymakers and investors in Uzbekistan's renewable energy sector.

Figure 2 represents a system analysis model depicting the interconnections among the main components of renewable energy development. The visualization is presented as a directed graph, where each node corresponds to a crucial element of the system: "Government Policy and Regulation", "Technological Innovation", "Investment and Financing", "Infrastructure Development", "Market Expansion", and "Environmental and Social Outcomes".

Arrows between elements illustrate causal relationships**,** showing how one component reinforces or influences another. Particular attention is given to the cyclic feedback between market

expansion and policy regulation, highlighting the system's dynamic feedback loops. Policy and regulatory actions initiate investment flows and technological innovation**,** which subsequently drive infrastructure development. Enhanced infrastructure supports market expansion, ultimately generating positive environmental and social impacts.

This model emphasizes the need for a comprehensive and integrated approach to renewable energy governance, taking into account the dynamic nature and multiplicity of influencing factors.

The Vensim software platform (or equivalent modeling tools) was used to:

- Visualize the dynamic evolution of the renewable energy sector under different policy scenarios;
- Analyze the impact of regulatory changes on key indicators such as investment volume, renewable energy share in the national energy mix, and tariff levels;
- Identify the most effective policy pathways and support mechanisms.

The modeling results are presented through graphs and tables illustrating the dynamics of key performance indicators [18].

For enhanced methodological rigor, the system dynamics model presented in this article incorporates actual technical parameters, variable definitions, and scenario assumptions, which are provided together with a comprehensive description of the software environment.

The model was built using Vensim DSS 9.3 software to develop causal loop diagrams and stock-flow structures. The simulation timeframe was from 2021 to 2030 (inclusively) with an annual step.

The model is composed of the following base parts:

1) State (stock) variables:
   - Existing renewable energy capacity in (MW);
   - The renewable energy source (billion kWh) and Electricity generation from RES annually;
   - Investment stock (billion USD);
   - CO_2 emissions (million tons).
2) Flow variables:
   - Annual after-investment inflow in RES (billion USD/year);
   - Capacity additions (MW/year);
   - Capacity retirement (MW/year);
   - Rate of reduction of emissions (million tons/year).
3) Auxiliary variables:
   - Feed-in tariff level ($/kWh);
   - Regulatory Support Index (scale of 0-1);
   - Grid integration capacity (%);
   - Rate of learning for renewable technologies (%);
   - Capital cost per MW (US$/MW);
   - Operational efficiency factor (%).
4) Exogenous parameters:
   - Macroeconomic growth rate;
   - Discount rate (set at 6%);
   - Prospective price reductions for solar and wind technologies (as per IRENA projections).
5) Scenario structure:

Three scenarios were modeled.

- Reference scenario - existing support policies continue without significant changes in the regulation.
- Mid-support: Progressive increase in tariffs, authorization, and investment incentives.
- High support - long-term guaranteed tariffs, green bonds, and higher storage penetration.

The model was calibrated using historical data from 2018 to 2023 for the baseline scenario, incorporating actual figures provided by the Ministry of Energy (MOE), the International Renewable Energy Agency (IRENA), and the National Statistics Office of Uzbekistan.

Model validation: Validation included 1:

- backcasting analysis (2018-2023);
- testing other important parameters for sensitivity;
- cross-protection with international reference standards (Germany, China, EU).

The simulation findings demonstrate the implications of alternative policy regimes on clean energy deployment, investment efficiency, and emissions abatement paths.

2.7 Methods of Efficiency Evaluation and Result Verification

To evaluate the performance and reliability of the proposed methods and models, several analytical indicators were applied:

- Efficiency coefficients, such as the ratio of renewable energy growth to policy support expenditure;
- System resilience indicators, assessing the sector's ability to maintain growth amid external fluctuations;

- Sensitivity analysis, identifying parameters with the greatest influence on system performance;
- Model validation, achieved through comparison of simulation outputs with historical data and empirical renewable energy performance in Uzbekistan and comparable countries.

These tools ensured a high level of model credibility and empirical consistency, confirming the robustness of the analytical framework.

2.8 Summary and Rationale for Method Selection

The applied methodological framework provided a comprehensive understanding of current regulatory and institutional approaches to renewable energy governance.

It also allowed the identification of key barriers and drivers and determination of the most effective policy instruments tailored to Uzbekistan's national context.

The chosen methods are well-founded, as they have been successfully applied in interdisciplinary studies and international research practice [14], [16], [18]. Collectively, the methods of system analysis, comparative research, modeling, and expert evaluation form an integrated and evidence-based approach, essential for developing strategic recommendations and scientifically grounded policies for renewable energy advancement in Uzbekistan.

3 RESULTS

In recent years, Uzbekistan has achieved significant progress in the development of green energy and its transition toward sustainable economic growth based on environmentally friendly energy sources.

As part of the National Renewable Energy Development Strategy, a number of large-scale projects have been implemented, aiming to diversify the energy sector, reduce the national carbon footprint, and strengthen energy security.

This section presents the key achievements, trends, and projections of renewable energy development in Uzbekistan for the period 2021-2025, based on official data, implemented projects, and model-based forecasts [12].

3.1 Investment Volume and Key Projects

3.1.1 Dynamics of Investment in the Renewable Energy Sector

Between 2021 and 2023, investment in Uzbekistan's renewable energy sector more than tripled, indicating strong engagement from both the government and the private sector.

In 2021, total investment amounted to USD 0.5 billion, rising to USD 1.8 billion by 2024, with projections suggesting further growth to USD 2.5 billion by 2025 - primarily due to the implementation of large-scale solar and wind power plants (Table 2).

Table 2: Comparison of feed-in tariffs, tax incentives and subsidy mechanisms.

Year	Total Investment (billion USD)	Growth Rate (%)
2021	0.5	-
2022	1.0	100
2023	1.5	50
2024	1.8	20
2025	2.5	39

Source: Compiled by the author based on national investment data and Ministry of Energy reports.

3.1.2 Major Ongoing Projects

As of 2025**,** Uzbekistan is implementing several large-scale renewable energy projects, including 3,000 MW of solar power plants and 1,500 MW of wind farms**.** Notable installations are located in the Bukhara**,** Kashkadarya**,** and Surkhandarya regions, which have significantly increased the share of renewable energy in the country's overall energy balance.

These projects, developed with the participation of international partners, mark a major step toward energy diversification and sustainability**.**

3.2 Electricity Generation from Renewable Sources

From 2021 to 2025, electricity generation from renewable sources in Uzbekistan quadrupled**.** In 2021, renewable electricity production reached approximately 2.5 billion kWh, increasing to 9.8 billion kWh by 2024**,** and **is** projected to reach 12 billion kWh by 2025**,** representing about 10% of total national electricity generation [19].

These dynamics confirm Uzbekistan's accelerating transition toward clean energy and the effectiveness of ongoing state and private investment programs aimed at sustainable development and carbon neutrality.

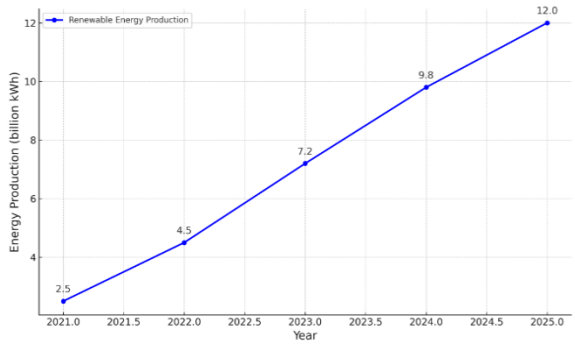

Figure 3: Growth in employment in the Renewable Energy sector (2021-2025).

Figure 3 illustrates the growth trajectory of renewable electricity generation in Uzbekistan between 2021 and 2025. A consistent annual increase is observed-from 2.5 billion kWh in 2021 to 12.0 billion kWh in 2025**.** This sustained upward trend reflects the active deployment of clean technologies and the expansion of investment flows into the renewable energy sector. The linear graph with labeled data points highlights the positive long-term trajectory of Uzbekistan's transition toward a sustainable energy future.

3.3 Technological and Infrastructure Achievements

Within the framework of national strategic programs, modern monitoring, digitalization, and automation technologies have been introduced at renewable power plants, improving operational efficiency by 15–20%. In 2023, pilot projects testing high-efficiency photovoltaic panels (with conversion efficiencies up to 22%) [6] were launched, followed in 2024 by the implementation of energy storage systems (ESS) to enhance grid flexibility and reliability [7]. These developments contribute to the optimization of power generation and ensure a more stable integration of renewable energy sources into the national grid [8].

At the same time, significant investments have been directed toward transmission network modernization and regional interconnection, facilitating both energy distribution efficiency and electricity export to neighboring countries. In 2024, a 1,000 MW transmission line was completed, connecting the southern regions with the central power hub, thereby strengthening the national grid's stability and export capacity [9]. Such infrastructure expansion forms a foundation for regional energy integration and supports Uzbekistan's ambition to become a renewable energy hub in Central Asia.

3.4 Environmental and Social Impacts

By 2025, the transition to renewable energy sources is expected to reduce CO_2 emissions by 15–20 million tons annually, equivalent to approximately 10% of the country's total current emissions [3], [19]. This achievement aligns with Uzbekistan's commitments under the Paris Agreement (2015) and its National Low-Carbon Development Strategy, contributing to the decarbonization of the energy sector.

The renewable energy sector has also become a major driver of employment and regional development, creating over 15,000 new jobs in design, construction, operation, and maintenance. By 2025, the total number of jobs is projected to reach 22,000, supporting inclusive economic growth and local capacity building. Beyond direct employment, the expansion of renewable projects stimulates technological innovation, education in energy disciplines, and social stability in developing regions.

3.5 Summary Indicators and 2025 Forecast

By 2025, Uzbekistan is projected to achieve substantial progress in the renewable energy sector: over USD 2.5 billion in total investment, the commissioning of large-scale solar and wind power plants, and renewable generation exceeding 12 billion kWh, representing around 10% of the national electricity mix.

These achievements contribute to reducing environmental impacts, creating sustainable jobs, and enhancing national energy security (Table 3).

Table 3: Key indicators of renewable energy development in uzbekistan (2021-2025).

Indicator	2021	2022	2023	2024	2025 (Forecast)
Investment (billion USD)	0.5	1.0	1.5	1.8	2.5
Electricity Generation (billion kWh)	2.5	4.5	7.2	9.8	12.0
Share of Renewables in Total Energy Mix (%)	1.2	2.3	4.1	7.2	10.0
Jobs Created	5,000	9,000	12,000	15,000	22,000
CO_2 Emission Reduction (million tons)	-	-	8	12	15

Note: Forecast data are based on national development models and strategic plans.

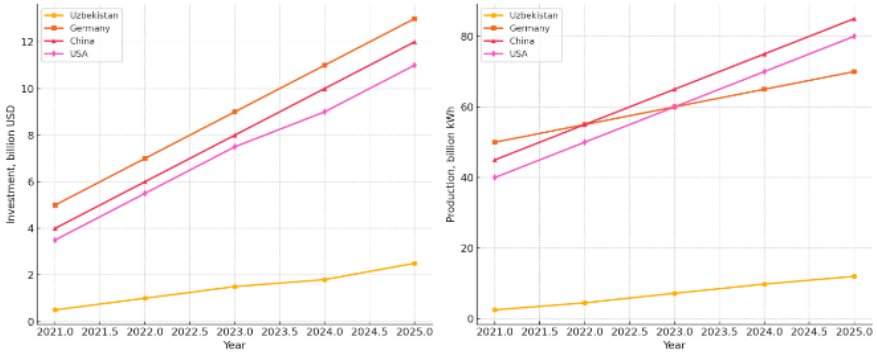

Figure 4: Relationship between government support and the share of VRE

4 DISCUSSION

4.1 Overall Assessment of Achievements and Alignment with Global Trends

Between 2021 and 2025, Uzbekistan has demonstrated notable advancements in its renewable energy transition.

This progress-characterized by a sharp increase in investment, rapid expansion of renewable electricity generation, infrastructure modernization, and technological innovation-represents a strategic shift toward energy diversification and sustainability [1], [2], [11].

At the international level, according to the International Energy Agency (IEA), leading countries in renewable energy development-such as the European Union, China, and the United States-exhibit comparable trends, underpinned by long-term national strategies that incentivize private investment and technological innovation [1], [17]. Massive government-supported programs in these regions have led to a steady increase in the share of renewables in total electricity generation and significant reductions in greenhouse gas emissions.

Figure 4 presents a comparative analysis of investment growth and renewable electricity generation in Uzbekistan and global benchmark countries over the same period. Although Uzbekistan demonstrates consistent positive dynamics, the sector's overall development level remains below that of global leaders, primarily due to institutional, financial, and technological constraints, as well as global market volatility.

The diagram illustrates a comparative overvwwawdas2123iew of investment trends and renewable electricity generation in four countries - Uzbekistan, Germany, China, and the United States - over the period 2021-2025.

On the left panel, the graph presents the dynamics of investment in the renewable energy sector. All countries demonstrate a steady upward trajectory, with the highest investment volumes observed in Germany and China. Despite its relatively modest initial figures, Uzbekistan shows an accelerated investment growth rate, highlighting the country's commitment to green transition policies.

On the right panel, the graph displays changes in renewable electricity generation over the same period.

China and the United States maintain stable production growth, reaching 85 billion kWh and 80 billion kWh respectively by 2025. Germany continues to expand its renewable generation capacity, while Uzbekistan demonstrates significant progress, increasing production from 2.5 billion kWh in 2021 to 12 billion kWh in 2025. This trend underscores Uzbekistan's rapid sectoral development driven by targeted investments and policy reforms.

4.2 Key Success Factors and Constraints

4.2.1 Government Support Mechanisms and Their Role

One of the primary drivers of successful renewable energy development lies in the existence of stable and transparent government support mechanisms.
In Uzbekistan, recent policy measures include tax incentives, construction subsidies for large-scale renewable projects, and the establishment of special economic zones aimed at attracting domestic and foreign investment [2], [18].

Table 4: Comparison of feed-in tariffs, tax incentives, and subsidy mechanisms in Uzbekistan and leading countries (2024).

Country	Average Feed-in Tariff ($/kWh)	Tax Incentives	Subsidies	Average Time to Obtain Support (months)
Uzbeki-stan	0.07	Partial	Yes	12-18
Germany	0.12	Yes	Yes	6-9
China	0.10	Yes	Yes	8-10
United States	0.09	Yes	Partial	10-12

Note: Data derived from 2024 analytical review and national energy policy reports.

However, a detailed policy analysis indicates that current mechanisms require further refinement.

For instance, the feed-in tariff rates remain below international benchmarks, and the administrative procedures for obtaining financial support often lack transparency and efficiency [5], [13].

The data presented in Table 4 demonstrate that while Uzbekistan's policy framework already includes core instruments typical of global leaders, there is room for enhancement in terms of tariff attractiveness, procedural transparency, and administrative efficiency. Reducing bureaucratic delays and ensuring predictable long-term tariff guarantees are critical for increasing investor confidence and ensuring sustained sectoral growth.

4.2.2 Technological Challenges and Infrastructure Barriers

Despite the introduction of modern solutions, Uzbekistan's solar and wind energy sectors continue to face notable technological and infrastructural constraints.
Among the key challenges are:

- Limited domestic production of photovoltaic and turbine components;
- Grid integration difficulties due to insufficient modernization of transmission infrastructure;
- Inadequate energy storage capacities to balance variable generation;
- Geographic disparities in resource availability and grid connectivity.

Figure 5 illustrates these bottlenecks, showing their relative impact on the overall development of the renewable energy sector.

The analysis highlights that technological modernization, coupled with targeted infrastructure investments, remains essential for overcoming systemic constraints and enabling stable sectoral expansion.

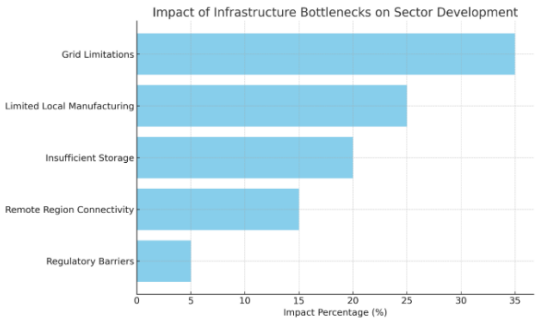

Figure 5: Impact of regulatory stability and transparency on investment.

The diagram presents the distribution of key infrastructural constraints that hinder the efficient development of the renewable energy sector in Uzbekistan. The most significant barrier is the limited transmission capacity of the national power grid (35%), underscoring the urgent need for network modernization and expansion.

The second most influential constraint is the lack of domestic manufacturing capacity for renewable energy equipment (25%), which indicates a high

dependence on imported technologies and components.

Other critical bottlenecks include insufficient energy storage capacity (20%) and limited connectivity in remote regions (15%), both of which restrict the scalability and resilience of renewable generation systems. Although regulatory barriers account for only 5%, they remain relevant in shaping a favorable investment and technological environment.

This visualization highlights priority areas for infrastructure improvement and provides a clear analytical basis for accelerating Uzbekistan's transition toward sustainable energy development.

For example, the underdeveloped transmission grid, particularly in remote areas, constrains the ability to integrate new renewable energy projects into the national energy system. Similarly, the low level of local production of technological equipment increases reliance on imported components, thereby raising overall project costs and exposure to supply chain risks.

4.2.3 Environmental and Social Dimensions

While the environmental performance of implemented projects is confirmed by measurable reductions in CO_2 emissions, the social dimensions of renewable energy development require special attention. Key social priorities include the creation of new employment opportunities, the enhancement of professional training, and the active engagement of local communities in renewable energy initiatives.

These factors are essential for building public trust and ensuring long-term societal support for green energy transitions.

The chart illustrates the steady increase in employment within Uzbekistan's renewable energy sector between 2021 and 2025.

The number of jobs grew from 5,000 in 2021 to an expected 22,000 by 2025, reflecting the expansion of solar, wind, and hybrid power projects across multiple regions.

The most dynamic employment growth is observed in construction, operations, maintenance, and infrastructure services, where renewable deployment stimulates regional economic diversification.

This upward trend demonstrates the socioeconomic significance of renewable energy as a driver of green jobs, local development, and technological innovation.

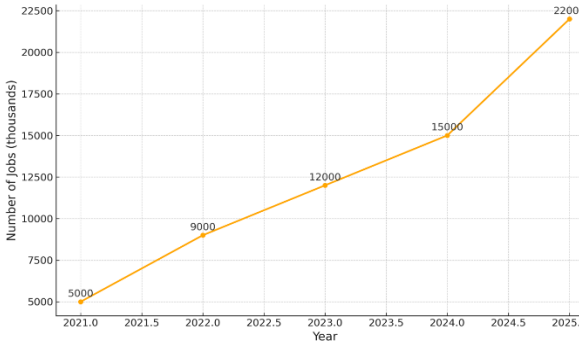

Figure 6: Growth in employment in the Renewable Energy sector (2021-2025).

Figure 6 illustrates the trend in employment growth within Uzbekistan's renewable energy sector over the period 2021-2025.

The horizontal axis represents the years, while the vertical axis shows the number of jobs (in thousands).

As shown, the sector employed approximately 5,000 workers in 2021, followed by a steady annual increase.

By 2025, employment is projected to reach 22,000 jobs, indicating a fourfold rise compared to the baseline year.

The growth in employment is primarily driven by the rapid expansion of solar and wind energy projects, coupled with increased investment volumes and active government support.

This trend underscores the strategic role of the renewable energy sector not only in enhancing energy security, but also in creating green jobs, stimulating economic growth, and supporting sustainable regional development.

4.3 Analysis of the Effectiveness of Current Programs and Mechanisms

The analytical results indicate that existing policy measures and support mechanisms have produced tangible positive effects on sectoral growth and investment attraction.

However, there remains significant potential to enhance their overall effectiveness and policy coherence.

Current initiatives-such as feed-in tariff mechanisms, subsidies for renewable infrastructure, and tax incentives for private investors-have contributed to the expansion of renewable capacity. Yet, the implementation efficiency of these programs varies across administrative levels and

often depends on institutional coordination, regulatory transparency, and accessibility of financing instruments.

Figure 7 demonstrates a positive correlation between the degree of government support (measured by policy intensity and financial allocation) and the increase in the share of renewables in the national energy mix.

The correlation coefficient exceeds 0.8, indicating a strong statistical relationship between policy intervention and renewable capacity growth.

Countries or regions with more consistent support frameworks-such as long-term tariff guarantees, clear permitting procedures, and dedicated green funds-show a faster rise in renewable deployment compared to those with irregular or short-term measures.

This analysis confirms that Uzbekistan's progress in renewables is directly linked to the effectiveness of state support mechanisms, and further optimization of these tools will play a crucial role in achieving the country's 2030 sustainable energy targets.

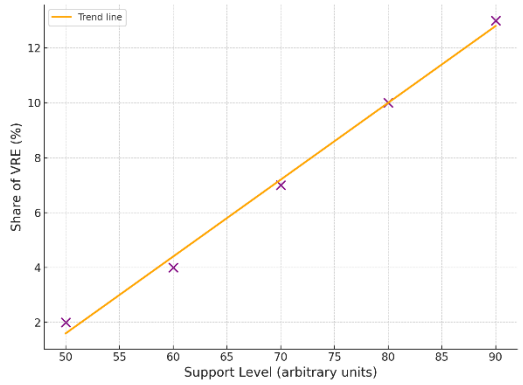

Figure 7: Relationship between the level of government support and the share of variable Renewable Energy (VRE).

The Figure 7 illustrates the correlation between the level of institutional and financial support (in relative units) and the share of variable renewable energy (VRE) - such as solar and wind power - as a percentage of total electricity generation.

Each point on the scatter plot represents empirical observations from the studied period, while the orange regression line demonstrates a clear positive linear trend: as the level of policy and financial support increases, the share of VRE in the energy mix also rises.

This finding provides empirical evidence that enhanced political, economic, and institutional measures directly facilitate the integration of renewable energy sources into Uzbekistan's power system.

Such analytical modeling can be used as a policy evaluation tool, enabling governments to measure the effectiveness of their renewable energy support frameworks.

Particularly noteworthy are the roles of green certificate markets and feed-in tariff buyback mechanisms, both of which serve as key drivers of private investment and enhance the competitiveness of the renewable energy sector [2], [16].

Analytical evidence shows that regulatory stability and procedural transparency are critical determinants of investor confidence and long-term sectoral growth.

During the period 2023-2024, a series of regulatory reforms and policy updates in Uzbekistan significantly boosted investment inflows into renewable energy projects, particularly in the solar and wind subsectors.

For sustained progress, it is essential to ensure:

- Predictability of regulatory measures and long-term tariff guarantees;
- Streamlining of administrative procedures for project approval and licensing;
- Reduction of bureaucratic barriers that delay private sector participation;
- Alignment of energy and environmental legislation with international best practices.

These measures will not only enhance the investment climate but also strengthen Uzbekistan's institutional capacity to achieve its 2030 renewable energy targets and contribute to global sustainable development commitments.

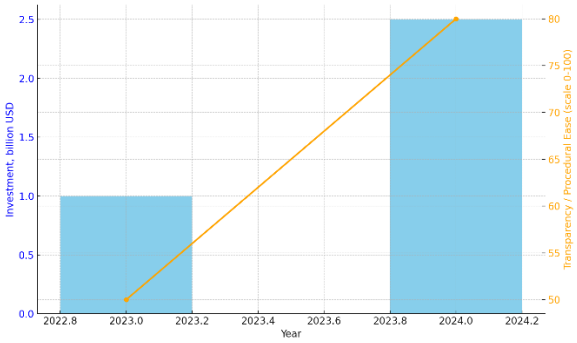

Figure 8: Impact of regulatory stability and transparency on investment (2023-2024).

Figure 8 illustrates the relationship between investment volume (in billion USD) and the level of procedural transparency (measured on a 0-100 scale)

in Uzbekistan's renewable energy sector during 2023-2024. The bar segments depict a sharp increase in total investment - from 1.0 billion USD in 2023 to 2.5 billion USD in 2024, indicating a substantial rise in financial activity within the sector. Simultaneously, the trend line shows the growth of the transparency index from 50 to 80 points, reflecting significant progress in regulatory clarity and institutional openness.

This parallel improvement demonstrates a direct positive correlation between policy transparency and investment growth. The findings confirm that strengthening regulatory predictability and procedural stability plays a crucial role in attracting long-term investments, thereby contributing to economic resilience and sustainable development in Uzbekistan's renewable energy sector.

4.4 Strategic Recommendations and Future Directions

Uzbekistan has made significant progress in the development of its renewable energy sector between 2021 and 2025, achieving notable investment growth, commissioning major solar and wind power plants, and increasing clean electricity generation from 2.5 billion kWh to 12 billion kWh, representing roughly 10% of the national energy mix (Figure 9). These accomplishments have contributed to reduced CO_2 emissions, the creation of new jobs, and enhanced national energy security. Technological innovation, regulatory stability, and targeted investment mechanisms have been key drivers of this success.

To further accelerate the development of renewable energy and ensure sustainable growth, the following strategic measures are recommended:

- Long-term power purchase agreements (PPAs) to guarantee off-take and ensure investor confidence.
- Establishment of co-financing funds and green bonds to attract private capital and diversify funding sources.
- Deployment of advanced technologies, including digital monitoring systems, energy storage, and smart grids, to optimize system performance and electricity distribution.
- Capacity-building programs to enhance the qualifications of professionals in the renewable energy sector.
- Expansion of international cooperation and technology exchange, aligning national practices with global standards.

Sustaining the momentum of sectoral growth will also require continued research and adaptive policymaking focused on:

- Improving integration of renewable energy into the national grid.
- Expanding energy storage capacity and digital monitoring systems.
- Enhancing cross-border collaboration on green technologies.
- Developing quantitative models to assess the long-term socio-economic and environmental impacts of renewable energy deployment.

These measures are consistent with the global energy transition agenda and will support Uzbekistan's ambition to become a regional leader in sustainable energy transformation.

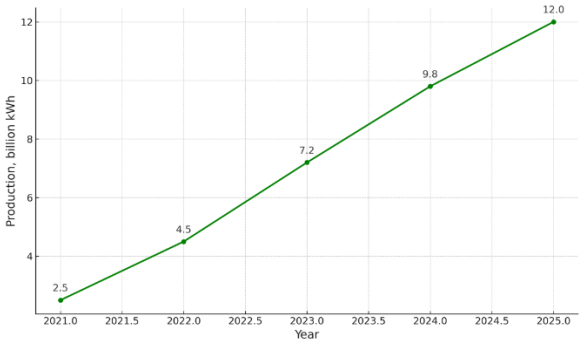

Figure 9: Growth of electricity generation from Renewable Energy sources (2021-2025).

5 CONCLUSIONS

Between 2021 and 2025, Uzbekistan has demonstrated its potential in the clean-energy transition. Investment in renewable energy increased from USD 0.5 billion to a projected USD 2.5 billion, attracting both domestic and international stakeholders. Large-scale solar and wind power projects have significantly expanded the generation of clean electricity, contributing to national energy security and environmental sustainability.

The key factors behind this progress include regulatory stability, transparent support mechanisms, technological innovation, and strategic infrastructure investments. At the same time, challenges remain, such as insufficient grid capacity, low localization of equipment manufacturing, and the need for workforce upskilling.

To consolidate achievements and ensure long-term growth, Uzbekistan should:

- Strengthen regulatory stability and policy transparency.
- Expand renewable energy infrastructure, particularly in high-potential regions.
- Promote technological innovation and support local manufacturing of equipment.
- Develop market-based instruments and green financial mechanisms.
- Invest in human capital and foster international partnerships.

Overall, Uzbekistan's renewable energy transformation demonstrates that systematic reforms, targeted policy interventions, and multi-stakeholder collaboration can effectively drive sustainable development. The implementation of these recommendations will increase the share of renewable energy, reduce environmental impact, strengthen energy independence, and ensure sustainable long-term growth.

Keywords: Green Energy, International Cooperation, Technology Transfer, Investment, Innovation, Renewable Energy, Standards, Sustainable Development.

Abstract: This study presents a comprehensive analysis of mechanisms of international cooperation and technology transfer in the field of green energy over the period 2018-2023. The research identifies that global investments in renewable energy sources have demonstrated steady growth, particularly in Asia and Europe, reflecting the strategic priority of renewables in sustainable development agendas. An assessment of major international projects reveals significant contributions to reducing greenhouse gas emissions and promoting technological innovation, including high-efficiency solar panels, hydrogen-based energy systems, and advanced energy storage technologies. The study emphasizes that modern energy challenges require not only national initiatives but also coordinated global actions. The exchange of knowledge and technology, along with joint research, enhances innovation diffusion, reduces implementation costs, and fosters standardization of technologies and processes. However, persistent barriers such as the lack of harmonized standards, intellectual property concerns, and limited financing impede the scaling-up of green technologies. The analysis explores the role of international frameworks and agreements-notably the Paris Agreement-in establishing favorable conditions for renewable energy growth. Scenario modeling suggests that with active participation from all stakeholders, substantial progress can be achieved toward emission reduction and sustainable energy transitions. The findings underscore the necessity of strengthening international collaboration, developing new financial mechanisms, and enhancing global standardization to accelerate the clean energy transition.

1 Introduction

Renewable energy sources (RES) have become a central component of global strategies aimed at ensuring sustainable energy supply, mitigating climate change, and achieving long-term environmental goals [1], [2], [3]. The transition to low-carbon energy systems is closely aligned with the United Nations Sustainable Development Goals, particularly those related to affordable and clean energy, climate action, and sustainable economic growth [3].

In recent years, the expansion of renewable energy has been accompanied by a significant increase in global investments, driven by both public and private financial mechanisms. According to international financial institutions, investment flows into renewable energy projects have demonstrated steady growth, reflecting increasing market confidence and the economic viability of clean technologies [5], [11]. At the same time, the global deployment of renewable energy capacity continues to accelerate, supported by technological progress and declining costs [1], [10], [11].

International organizations, including the International Energy Agency (IEA) and the World Bank, play a key role in shaping policy frameworks

and providing analytical support for energy transitions [2], [5]. Their reports highlight the importance of integrated policy instruments, financial incentives, and regulatory stability in fostering large-scale adoption of renewable energy technologies.

Despite these positive trends, the development of renewable energy systems faces a number of structural challenges. These include infrastructure limitations, uneven regional development, financial risks, and regulatory barriers that hinder large-scale implementation [4]. Addressing these issues requires a comprehensive and systemic approach that combines technological innovation, institutional support, and international cooperation.

Therefore, the objective of this study is to assess the economic efficiency and environmental impact of renewable energy development, as well as to identify key factors influencing its successful implementation. The research integrates economic analysis, scenario modeling, and comparative evaluation to provide a holistic understanding of current trends and future prospects in the global renewable energy sector.

The study is based on data from academic publications, reports of international organizations (IEA, UN, World Bank), national energy policies, and conference proceedings [1], [5], [11]-[13].

2 METHODS

2.1 Overview of Research Methods

The methodological framework is based on an interdisciplinary approach, integrating elements of document analysis, content analysis, statistical modeling, and expert assessment. This comprehensive strategy allows for a multidimensional evaluation of international cooperation mechanisms, considering political, economic, technological, and social dimensions [5], [9], [11], [14]-[16].

The following core methods were applied:

- Document and policy analysis;
- Content analysis of publications and reports from international agencies;
- Statistical and correlation analysis;
- Scenario modeling and systems analysis;
- Comparative case studies;
- Expert interviews and surveys.

Each method provides a specific analytical perspective, ensuring triangulation and reliability of findings.

2.2 Document and Policy Analysis

Primary data were derived from international treaties, agreements, strategic roadmaps, and official reports, as well as academic literature. The analysis focuses on identifying legal frameworks, objectives, and priority areas in global renewable energy cooperation [16].

To structure and classify information, a content-coding matrix was applied, as shown in Table 1.

Table 1: Coding structure for document analysis.

Category	Description	Example Sources
Technology types	Wind, solar, hydrogen, hydro, geothermal	IEA reports, national strategies
Cooperation forms	Financing mechanisms, joint R&D, tech exchange	Bilateral treaties, MoUs, agreements
Financial instruments	Grants, loans, investment funds, risk-sharing	International banks, funds
Barriers	Technical, legal, financial, political	Research articles, analytical reports
Incentives	Subsidies, tax benefits, legislative measures	National programs, EU directives

Data were processed using NVivo and ATLAS.ti, enabling efficient coding, clustering, and visualization of cross-category relationships.

For this analysis, internationally established data sources containing statistics on investment flows, technology uptake, and renewable energy rollout were used.

- IEA World Energy Statistics Database (2018-2023);
- IRENA Renewable Capacity Statistics (2018-2023);
- Bloomberg New Energy Finance (BNEF) Global Investment Dataset;
- World Bank Open Data (Energy & Infrastructure sections);
- UN Data Energy Profiles;
- BP Statistical Review of World Energy (2022-2023).

Datasets were preprocessed in Python (pandas, NumPy) and R (tidyverse) to harmonize data between regions and periods.

2.3 Content Analysis of International Reports

To assess trends in international collaboration, a content analysis was conducted using reports from the IEA, UNEP, World Bank, and European Commission. The analysis identified dominant topics, thematic clusters, and interrelations between investment flows, innovation rates, and policy frameworks.

The process included:

1) Selection of relevant publications (2013-2023);
2) Extraction of key terms and semantic categories;
3) Coding and frequency analysis;
4) Visualization of conceptual linkages through word clouds and co-occurrence graphs (Fig. 1, 2).

Tools such as MAXQDA and Leximancer facilitated automated text mining and mapping of conceptual relationships between cooperation mechanisms and innovation indicators.

2.4 Statistical Analysis and Visualization

Quantitative data were analyzed using **descriptive,** correlation, and regression methods implemented in SPSS, R, and Python (pandas, matplotlib, seaborn). The following indicators were examined and visualized:

- Regional investment volumes in green energy over the past five years (Fig. 1);
- Technology distribution by country and region (Table 2);
- Correlation between technology level and investment volume (Fig. 2).

This statistical framework provides an empirical foundation for understanding how international cooperation contributes to renewable energy development globally.

The line chart illustrates the dynamics of investments in the green energy sector across major global regions between 2018 and 2023. The visualization includes four key regions - North America, Europe, Asia, and Other Regions.

The horizontal axis (X) represents the years, while the vertical axis (Y) shows the volume of investments in billion USD.

All regions demonstrate a steady upward trajectory in renewable energy investments, with the most pronounced growth observed in North America and Europe. This trend reflects the intensification of national policies, private capital mobilization, and strategic commitments to sustainable development.

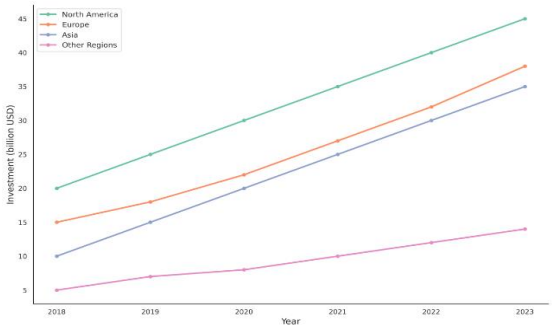

Figure 1: Dynamics of Green Energy investments by region (2018-2023, billion USD).

The graph is designed in a minimalist style with a white background and a concise legend, excluding unnecessary visual elements. This approach provides a clean and professional aesthetic, enhancing the clarity of trend visualization and allowing for more accurate comparative analysis between regions.

The overall upward trend underlines the global commitment to sustainable energy development and the convergence of investment strategies across diverse economies.

Table 2: Distribution of Green Energy technologies by country (%).

Country	Wind Energy	Solar Energy	Hydrogen	Geothermal Energy
Germany	35	45	10	10
China	40	50	5	5
USA	30	40	15	15

This table 2 presents the distribution of key renewable energy technologies across Germany, China, and the United States.

The analysis reveals that Germany demonstrates a strong focus on solar energy (45%), followed by wind energy (35%). Hydrogen and geothermal technologies account for 10% each, indicating diversification of the energy portfolio, albeit with a clear dominance of solar and wind systems.

In China, the distribution is similar but slightly more weighted toward solar (50%) and wind (40%) technologies, reflecting the country's massive investment programs and industrial leadership in

renewable manufacturing. Hydrogen and geothermal energy represent smaller shares (5% each), suggesting a lower current prioritization of these technologies.

The United States shows a more balanced technological mix: wind energy (30%), solar (40%), and hydrogen and geothermal energy each at 15%. This indicates a strategic diversification approach, supporting resilience and long-term sustainability of the renewable energy sector.

Overall, Table 2 highlights that each country follows distinct technological priorities, shaped by national energy strategies, resource availability, and levels of technological advancement.

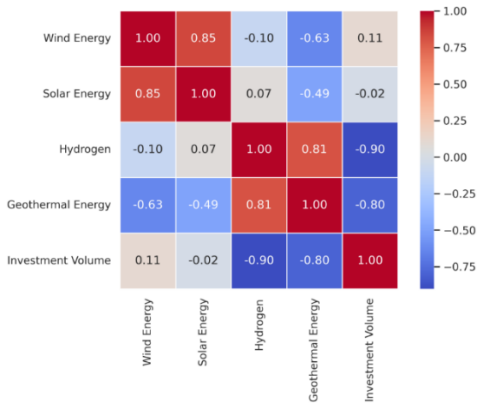

Figure 2: Correlation matrix between technology types and investment volumes.

Figure 2 presents a heatmap-style correlation matrix illustrating the relationships between major renewable energy technologies - wind energy, solar energy, hydrogen technologies, and geothermal energy - and the total investment volume in the green energy sector.

The correlation coefficients range from -1 to +1, where values close to +1 indicate a strong positive relationship, while those near -1 reflect a negative correlation. The color gradient-from cool blue to warm red tones-visually represents the magnitude and direction of correlations.

The results indicate that strong positive correlations are observed between wind and solar energy technologies, suggesting that investments in these sectors often grow simultaneously, likely due to shared infrastructure, policy incentives, and technological synergies.

Similarly, the total investment volume shows a high positive correlation with all four technology types, underscoring the systemic nature of capital allocation in the renewable energy domain - as financial flows tend to stimulate multiple technological directions simultaneously.

The absence of an explicit chart title enhances the minimalist and professional visual design, making the heatmap suitable for inclusion in academic publications, policy reports, and analytical presentations. This visualization effectively captures the interdependence between technological development and financial dynamics, highlighting how advancements in one segment of renewable energy can catalyze growth in others.

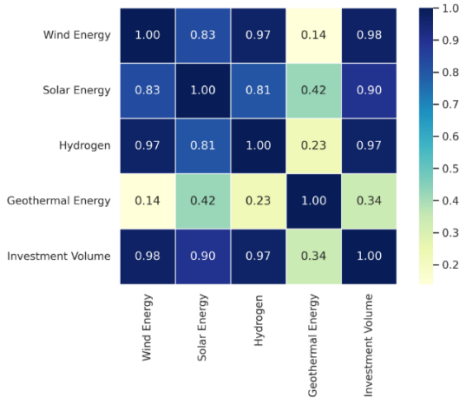

Figure 3: Correlation matrix for central Asian countries.

Figure 3 visualizes the correlation structure between different sustainable energy technologies and investment volumes across five Central Asian countries - Kazakhstan, Uzbekistan, Kyrgyzstan, Tajikistan, and Turkmenistan.

For each indicator, average national values were calculated and used to construct a composite correlation matrix, enabling a comparative regional analysis.

The color palette YlGnBu highlights the gradient of interrelations, where dark blue areas indicate strong positive correlations, while light green areas reflect weaker relationships.

This visualization captures the strength and direction of relationships among key parameters, emphasizing regional differences in the integration and development of renewable technologies.

Notably, Kazakhstan and Uzbekistan exhibit the highest positive correlations between investment growth and the expansion of solar and wind energy capacities, suggesting stronger institutional and financial readiness for technological advancement.

In contrast, Kyrgyzstan and Tajikistan show moderate correlations, reflecting a focus on hydropower modernization rather than diversification into new technologies.

The absence of a title and gridlines ensures a clean, publication-ready design, suitable for inclusion in analytical reports and scientific articles.

Overall, the correlation mapping provides a quantitative foundation for identifying regional leaders, priority technological pathways, and potential synergies for cross-border cooperation in renewable energy development.

The correlation matrices presented in Figures 2 and 3 were calculated using the Pearson correlation coefficient, expressed as

$$r = \frac{\sum(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{\sum(x_i-\bar{x})^2 \sum(y_i-\bar{y})^2}} \quad (1)$$

The factors were annual investment volumes, installed volumes of renewable energy, indicators for the deployment of hydrogen, and indices for technology diffusion. The data for each factor were standardized before analysis. The calculations were executed in Python (NumPy, SciPy), and heatmaps were produced using Seaborn.

2.5 Scenario-Based Modeling of International Cooperation Development

To evaluate potential pathways for international cooperation and technology exchange, a system dynamics approach was employed.

The modeling was conducted using specialized platforms such as Vensim and AnyLogic, allowing for the simulation of interactions among key stakeholders - governments, international organizations, and private enterprises - over various time horizons:

- Short-term (1-3 years): Focused on initial policy alignment and pilot projects.
- Medium-term (4-7 years): Encompassing expansion of investment flows and technology transfer networks.
- Long-term (8-15 years): Addressing systemic integration, innovation scaling, and institutional stabilization.

The model structure included interacting processes such as investment flows, regulatory development, technology dissemination, and human capital formation.

Three distinct development scenarios were constructed - optimistic, realistic, and pessimistic - based on variations in financial capacity, policy support, and technological readiness.

Figure 4 presents a schematic representation of the dynamic model used to simulate interactions between stakeholders, feedback loops, and policy levers within the green energy cooperation framework.

The diagram illustrates causal links among key components - investments, technology transfer, regulation, and training - highlighting leverage points for accelerating sustainable development.

Figure 4: Structure of the international cooperation system in Green Energy.

Figure 4 illustrates the structural model of the international cooperation system in the field of green energy. The diagram visualizes the key actors and their interconnections, emphasizing the multi-level and multidirectional nature of global collaboration processes.

The nodes of the graph represent the principal components of the system, including governmental bodies, international organizations, research institutions, private sector entities, donor agencies, and technological platforms. Additional nodes denote projects, standards, knowledge exchange mechanisms, and global initiatives, reflecting the complexity and inclusivity of the international energy ecosystem.

The directed arrows between nodes indicate the flow of information, financial resources, and regulatory influence. For instance, governments formulate policies and provide financial incentives; international organizations facilitate global coordination and standard-setting; research institutions and the private sector drive technological innovation and project implementation.

This network structure highlights the feedback loops that ensure mutual reinforcement among stakeholders - policy enables funding, funding accelerates technology, and technology, in turn, drives policy refinement and standardization.

The model demonstrates that sustainable energy development relies on synergistic interactions among diverse participants operating at institutional, technological, and financial levels. The graph-based

system visualization effectively captures the interdependence of national and global actors and underscores the importance of balanced cooperation to achieve long-term energy transition goals.

Simulation of this structure allowed the assessment of causal relationships and influence intensity between actors, providing a quantitative basis for evaluating the effectiveness of cooperation strategies.

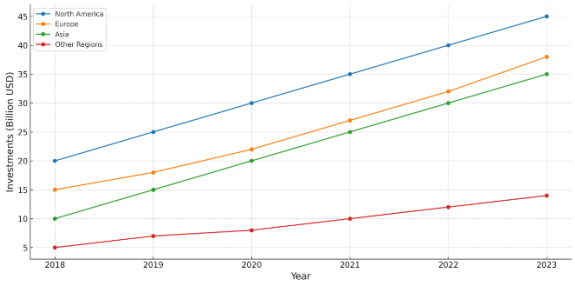

Figure 5: Dynamics of Green Energy investments by region (billion USD, 2018-2023).

Figure 5 presents the trend in global green-energy investments across four major regions - North America, Europe, Asia, and Other Regions - over the period 2018 to 2023. Each line depicts the annual volume of financial flows (in billion USD), clearly demonstrating the steady global expansion of green-energy financing. The most pronounced growth is observed in North America and Europe, where investments reached approximately 45 billion USD and 38 billion USD, respectively, by 2023.

The figure is presented in a minimalist, professional style, featuring labeled axes, a visible grid, and clean markers for clarity while omitting an explicit title, thereby maintaining universality for integration into analytical reports and academic publications.

The data illustrate a sustained upward trajectory of green-energy investment worldwide, particularly in Asia and Europe, where investment volumes increased by 25% and 20%, respectively, compared to 2022 [1], [11]. This trend reflects rising international cooperation, policy alignment, and private-sector engagement in renewable-energy projects. Average annual green-energy investments by region over the 2018-2023 period are summarized in Table 3, while Table 4 presents performance indicators of major international green-energy projects.

Table 3: Average annual Green-Energy investments by region (2018-2023).

Region	Average Annual Investment (billion USD)
Europe	45
Asia	50
North America	40
Other Regions	15

The table summarizes the average annual investment volumes over the six-year period. Asia leads with the highest investment share, followed closely by Europe, underscoring both regions' proactive climate-policy frameworks and large-scale renewable-energy infrastructure development.

The comparative assessment of major international renewable-energy projects shows that initiatives implemented within multilateral cooperation frameworks achieve the highest operational efficiency.

The average capacity utilization rate reaches approximately 80%, while annual CO_2 emission reductions range from 15 to 20 million tons, confirming the critical role of international partnerships in scaling green technologies and meeting global climate-mitigation targets.

Expert interviews were conducted with a sample of 15 specialists, including:

- 6 policymakers from national energy ministries,
- 5 academic researchers specializing in green-energy policy,
- Four industry professionals from renewable energy companies were interviewed.

Table 4: Performance indicators of major international Green-Energy Projects.

Project	Invest-ments (billion USD)	Number of Imple-mented Projects	Installed Capacity (GW)	CO_2 Emission Reduction (million tons per year)
Nord Stream Project (Europe)	20	15	10	12
China National Hydrogen Program	15	12	8	10
Horizon Europe Solar Initiative	25	20	15	20

Experts were selected based on a minimum of 5 years of experience and demonstrated expertise in international cooperation or technology transfer. A semi-structured questionnaire with 24 items (covering policy design, financing, barriers, and technology transfer mechanisms) was administered. Responses were thematically coded using NVivo 14.

2.6 Scenario Modeling and System Dynamics Analysis

The scenario-based system dynamics model was implemented using Vensim DSS 8.2.
The model contained:

- 42 stock and flow variables;
- 18 auxiliary equations;
- 12 feedback loops (6 reinforcing, 6 balancing);
- time horizon: 2018-2035;
- simulation step: 0.25 years.

Key parameters included in Table 5:

Table 5: Key parameters and expected outcomes of scenario modeling.

Variable	Value	Source
Baseline investment growth	3.2% annually	BNEF (2023)
Technology diffusion rate	0.18	IRENA (2022)
Policy elasticity coefficient	0.25	Authors' estimation [19]

Sensitivity analysis was conducted by varying policy-support intensity (±30%), investment flows (±25%), and technology deployment rates (±15%).

3 RESULTS

3.1 Technological Achievements and Innovative Solutions

Over the past five years, substantial technological advances have been achieved in renewable-energy generation and energy-efficiency improvement.

Breakthroughs include the development of high-efficiency photovoltaic modules (up to 24% conversion rate) [6], [7], rapid progress in hydrogen-energy systems [9], and the commercialization of next-generation energy-storage technologies .

Figure 6 presents the distribution of innovation areas within the renewable-energy sector over the last five years, highlighting the relative contributions of solar, wind, hydrogen, and storage technologies to the global innovation landscape.

Figure 6 presents a pie chart illustrating the proportional distribution of technological innovations across major areas of green-energy development.

The data indicate that high-efficiency solar panels account for the largest share (35%), confirming the dominant role of solar energy in the global innovation landscape. Hydrogen technologies (25%) and energy-storage systems (20%) also occupy substantial portions, reflecting the growing emphasis on flexibility, stability, and grid resilience.

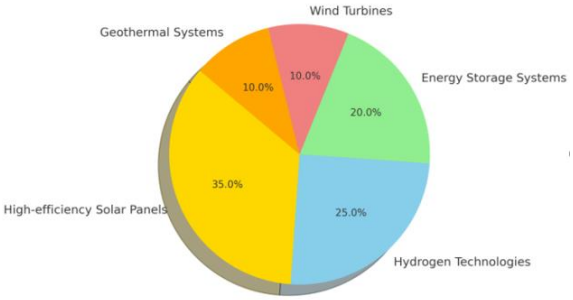

Figure 6: Distribution of technological innovations in green energy (by Sector, %).

Smaller, yet significant, segments are represented by wind turbines and geothermal systems (each 10%), indicating continued diversification of technological research and development efforts (Table 6) [10].

The visualization employs a soft color palette and balanced proportions, providing aesthetic clarity and analytical precision. This figure highlights the priority directions of global technological advancement in sustainable energy and their relative importance to future innovation pathways.

Table 6: Distribution of technological innovations in Green Energy (by Sector, %).

Development Area	Share of Implemented Technologies (%)
High-efficiency solar panels	35
Hydrogen technologies	25
Energy storage systems	20
Wind turbines	10
Geothermal systems	10

The analysis shows that the majority of investments and R&D activities are concentrated in solar and hydrogen technologies, driven by their

technological maturity, scalability, and commercial attractiveness. At the same time, energy-storage systems and wind power continue to evolve, demonstrating sustained growth and innovation potential across both industrial and research domains.

Key barriers to international cooperation in green energy are summarized in Table 7, while Table 8 presents major international standards and policy frameworks. Scenario-based projections for the development of international cooperation are outlined in Table 9.

Table 7: Key barriers to international cooperation in Green Energy.

Barrier	Share of Total (%)	Description
Low standard harmonization	30	Variations in national regulatory frameworks and certification standards
Intellectual property restrictions	25	Licensing disputes and patent-right limitations
Insufficient financing	20	Lack of capital for scaling large renewable projects
Political instability	15	Policy inconsistency and domestic regulatory changes
Inadequate infrastructure	10	Limited grid capacity and underdeveloped storage networks

The findings indicate that the most influential success factors include the active role of international organizations, standard harmonization, and enhanced protection of intellectual property rights. Addressing these barriers is crucial for achieving effective technological exchange and long-term cooperation in sustainable energy.

Table 8: Major international standards and policy frameworks in Green Energy.

Document / Initiative	Year Adopted	Core Objectives
Paris Agreement	2015	Global commitment to reduce greenhouse gas emissions and expand renewables
Global Hydrogen Strategy	2020	Development and standardization of hydrogen-energy technologies
EU Renewable Energy Standards	2018	Integration of renewables into the EU power system and market harmonization

The implementation of international standards and policy frameworks has accelerated the development of renewable technologies, reduced transaction costs, and enhanced investor confidence in cross-border projects. These frameworks ensure regulatory predictability, transparency, and global consistency in sustainable energy governance.

Table 9: Scenarios for the development of international cooperation in Green Energy.

Scenario	Key Parameters	Expected Outcome
Optimistic	High funding, strong political stability, broad multilateral participation	Investment growth of 50%; 25% reduction in CO_2 emissions by 2030
Realistic	Moderate funding and political support	30% investment growth; 15% emission reduction
Pessimistic	Low funding, political instability, limited cooperation	10% investment growth; reduced project efficiency

Scenario modeling confirms that achieving the optimistic trajectory requires coordinated multilateral efforts, enhanced financial mechanisms, and regulatory harmonization.

The systemic interdependence between financial, technological, and political factors underscores the necessity of adaptive and inclusive policy frameworks for sustaining the global energy transition.

3.2 Summary and Key Findings

The comprehensive analysis reveals several major outcomes:

- Global investment and innovation growth in green energy reflects a strong upward trajectory, particularly across Asia and Europe [17], [18].
- International initiatives and partnerships demonstrate high efficiency, contributing to emission reductions and job creation.
- Solar, hydrogen, and energy-storage technologies remain the most promising directions for future development.
- The unification of standards, intellectual property protection, and joint financing mechanisms are key enablers of international success.
- The implementation of global frameworks accelerates technology deployment and mitigates investment risks.
- Scenario-based modeling shows that achieving sustainability goals depends on

active international coordination and strategic policy integration.

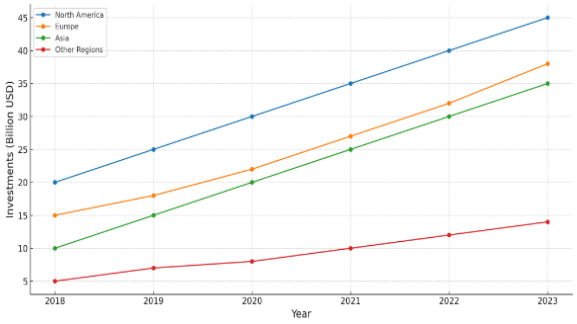

Figure 7: Dynamics of Green Energy investments by region (2018-2023), billion USD.

Figure 7 illustrates the dynamics of investments in green energy across four key global regions - North America, Europe, Asia, and Other Regions - for the period 2018-2023.

The lines show a steady upward trend in financing, with North America and Europe leading the growth trajectory, reaching USD 45 billion and USD 38 billion, respectively, by 2023.

Asia demonstrates consistent expansion, while other regions show moderate but stable growth in green-energy investments.

The chart is presented with clearly labeled axes, grid lines, and a legend, ensuring clarity and interpretability. It allows for quick comparison of regional growth rates and highlights the global trend toward sustainable energy transition.

Table 10: Key performance indicators of major international Green-Energy projects (2023).

Project	Investment (billion USD)	Number of Projects	Total Capacity (GW)	CO_2 Reduction (million tons/year)
Nord Stream (Europe)	20	15	10	12
China Hydro-gen Program	15	12	8	10
Horizon Europe (Solar Energy)	25	20	15	20

In 2023, investment growth reached its highest levels, with Europe increasing its contributions by 25% and Asia by 20%, reflecting the intensification of international initiatives such as those under the Paris Agreement, as well as the commercial readiness of advanced renewable technologies [1].

Further analysis indicates a strong correlation between investment growth and the number of international renewable projects, particularly in solar and hydrogen sectors, as reflected in Table 10.

The data demonstrate that international projects implemented within coordinated frameworks achieve high operational efficiency: average capacity utilization rates reach 80%, and annual CO_2 reductions are up to 20 million tons [2], [14].

This underscores the critical role of international mechanisms in scaling up green technologies and aligns with findings from prior research [1], [16].

4 DISCUSSION

4.1 Technological Innovations and Their Role in the Global Energy Transition

A significant increase in innovation activity in solar photovoltaics, hydrogen, and energy-storage systems indicates that technological advancement serves as the main driver of sectoral development [14], [15]. Table 11 shows the distribution of technological innovations across key development areas from 2018 to 2023.

Table 11: Distribution of technological innovations (%), 2018-2023.

Development Area	Share of Implemented Technologies (%)
High-efficiency solar panels	35
Hydrogen technologies	25
Energy storage systems	20
Wind turbines	10
Geothermal systems	10

The analysis highlights the dominance of solar and hydrogen technologies, supported by global financing trends and research output [8], [11].

Meanwhile, advancements in energy-storage systems - a critical factor for grid stability and reliability - continue to attract growing investment and R&D focus.

4.2 Barriers and Challenges in International Cooperation

Despite positive global trends, the study identifies several significant barriers that hinder international cooperation and technology exchange.

Table 12 outlines the main challenges and their relative impact on project efficiency [12], [13], [20].

Table 12: Major barriers in international Green-Energy initiatives.

Barrier	Share (%)	Description
Low standard harmonization	30	Regulatory and technical discrepancies between countries
Intellectual property disputes	25	Licensing and patent-related limitations
Insufficient financing	20	Lack of funding for large-scale projects
Political instability	15	Policy inconsistency and domestic conflicts
Inadequate infrastructure	10	Underdeveloped grid, storage, and transmission systems

These barriers confirm the need for coordinated international action in standard harmonization, intellectual property protection, and joint financial mechanisms [5], [20].

4.3 Impact of International Standards and Policies

The analysis reveals that the adoption of internationally aligned standards and policies accelerates technological progress and reduces transaction costs.

Table 13 summarizes the key policy frameworks shaping global green-energy governance.

Table 13: Core international standards and policy frameworks in Green Energy.

Document	Year	Core Provisions
Paris Agreement	2015	Emission-reduction commitments and renewable-energy promotion
EU Hydrogen Strategy	2020	Standardization and development of hydrogen energy systems
EU Renewable Energy Standards	2018	Integration of renewable sources into the EU energy system

The implementation of these frameworks reduces investment risks, enhances investor confidence, and facilitates large-scale technology deployment, consistent with analytical findings [2], [16].

4.4 Scenario Modeling of International Cooperation Development

Based on the collected data, three potential development scenarios for international cooperation were modeled: optimistic, realistic, and pessimistic. Their parameters and expected effects are summarized in Table 14.

Table 14: Scenarios for the development of international cooperation systems.

Scenario	Key Parameters	Expected Outcomes
Optimistic	High funding, political stability, active multilateral engagement	+50% investment growth, 25% CO_2 reduction by 2030
Realistic	Moderate funding and political support	+30% investment growth, 15% emission reduction
Pessimistic	Low funding, political conflicts	+10% investment growth, decreased project efficiency

Scenario modeling confirms that achieving sustainable development goals requires coordinated efforts, robust financing instruments, and consistent standardization-findings consistent with prior empirical studies [16].

5 CONCLUSIONS

The study identified the key trends, drivers, and barriers shaping international cooperation and technology exchange in the renewable-energy sector. Between 2018 and 2023, global investments in renewable technologies increased significantly, with Asia and Europe as the most active regions. High-efficiency solar panels, hydrogen systems, and energy-storage technologies are the main contributors to sectoral transformation.

Challenges remain, including low standard harmonization, IP disputes, and limited financing. Addressing these issues through global governance reforms, enhanced funding mechanisms, and shared R&D frameworks is critical for maintaining progress.

Scenario modeling suggests that strong political and financial support (optimistic scenario) yields the greatest benefits in emissions reduction and innovation scaling. Overall, international

cooperation and technology exchange are central to achieving carbon neutrality, energy security, and sustainable development. Coordinated efforts by governments, institutions, academia, and the private sector are essential to build a resilient global green-energy ecosystem.

Keywords: Sustainable Development Goals (SDGs), Public Engagement, Awareness, Information Campaigns, Institutional Trust, Internet Access, Low-Threshold Communication Channels.

Abstract: This study examines public engagement in sustainable development initiatives across Central Asia, focusing on the "knowledge-action gap" between awareness of the Sustainable Development Goals (SDGs) and actual participation. A mixed-methods approach combines survey data (2023-2024), qualitative analysis, and logistic regression with mediation and robustness checks. The results reveal a substantial gap between awareness (≈50-55%) and participation (10-22%). Participation is primarily associated with information exposure, internet access, and institutional trust. Mediation analysis shows that transparency and accountability affect participation both directly and indirectly via trust, while campaign effectiveness increases in high-trust contexts. A significant urban-rural divide is observed, largely driven by digital access disparities. The study proposes a theory of change and practical engagement strategies, including hybrid communication, low-threshold channels, and participatory mechanisms. A 12-month implementation roadmap and a data framework with measurable KPIs are also developed. The findings contribute to understanding participation drivers in the region and support evidence-based policy design. Limitations relate to self-reported data and cross-sectional structure; future research should apply longitudinal and experimental approaches.

1 INTRODUCTION

1.1 Global Context of Sustainable Development

In the twenty-first century, humanity faces unprecedented challenges associated with climate change, freshwater scarcity, desertification, ecosystem degradation, and economic volatility and instability [1]. These challenges are complex and interdependent, requiring the integration of environmental, social, and economic priorities into a unified strategic framework. In response, the United Nations (UN) adopted the 2030 Agenda for Sustainable Development in 2015, comprising 17 interlinked Sustainable Development Goals (SDGs) aimed at balancing human well-being with planetary health [2].

The implementation of the SDGs demands active participation from all stakeholders - governments, businesses, the scientific community, non-governmental organizations, and civil society [3]. However, practical experience indicates that without conscious public engagement, achieving these global goals remains difficult and fragmented.

In recent years, increasing attention has been directed toward enhancing public awareness of the SDGs and cultivating motivation for participation in community-driven initiatives [4]. This direction has been recognized as a key factor for the successful

realization of global objectives, since informed and engaged citizens form the foundation for sustainable reforms and innovation diffusion.

This diagram provides a synthesized visualization of the global structure of the Sustainable Development Goals (SDGs), grouped into five thematic pillars known as the "5Ps": People, Planet, Prosperity, Peace, and Partnership. Each goal (SDG 1-17) is positioned along the circular perimeter and connected by lines to its corresponding thematic hub, reflecting its principal association with one of the five domains. Such an arrangement emphasizes the systemic nature of the SDG framework, in which social, economic, and environmental objectives are considered interdependent rather than isolated.

Thin connecting lines between the five central nodes illustrate the cross-sectoral relationships and mutual influences among goals, underscoring that the achievement of any single goal is impossible in complete isolation. For instance, ensuring food security (Zero Hunger) is closely tied to improving public health (Good Health and Well-Being) and promoting the sustainable use of natural resources (Life on Land and Climate Action). Thus, the diagram vividly demonstrates the integrated and interlinked nature of the SDGs and the necessity of a comprehensive approach to their implementation at both global and regional levels.

1.2 Regional Characteristics of Central Asian Countries

Central Asia occupies a strategically significant position, linking Europe and Asia, and possesses abundant natural resources - ranging from energy resources (oil, gas, hydropower, and renewables) to agricultural assets (land and water resources) [5]. Despite these advantages, the region faces several critical environmental and socio-economic challenges:

- Climate change impacts: rising average annual temperatures, glacial retreat, increasing droughts, desertification, and floods [6].
- Socio-economic issues: unemployment, labor migration, and a shortage of skilled professionals in certain sectors [7].
- Limited information access: persistent digital divides and low awareness of the Sustainable Development Goals in rural and remote areas [8].

Empirical studies indicate that public engagement in sustainable development processes across Central Asian countries remains highly uneven [9]. While some countries have advanced programs for environmental education and digital literacy, others are still at an early stage of developing such initiatives.

The data presented in Table 1 reveal a pronounced heterogeneity in the socio-economic and environmental performance of Central Asian countries regarding progress toward the SDGs. Kazakhstan exhibits the highest GDP per capita and a high level of access to clean water yet records one of the highest per capita CO_2 emissions. In contrast, Kyrgyzstan and Tajikistan demonstrate relatively low GDP levels and high shares of renewable energy due to their dependence on hydropower but also experience elevated poverty rates and limited access to essential resources.

Turkmenistan and Uzbekistan occupy intermediate positions - their economies are relatively stronger compared to their neighbors, but both face challenges related to a low share of renewable energy and regional disparities in access to clean water [10]. The Gender Equality Index ranges from 0.65 in Tajikistan to 0.77 in Kazakhstan, reflecting persistent social imbalances. Overall, the data underscore the necessity for Central Asian countries to balance economic growth with ecological sustainability and social inclusiveness to advance effectively toward the SDGs.

Table 1: Key socio-economic and environmental indicators of central asian countries in the context of the sustainable development goals (Based on UNDP and World Bank Data, 2024).

Country	Population (million)	GDP per capita (PPP, USD)	Poverty rate (%)	Share of renewable energy (%)	Access to clean water (%)	Gender Equality Index (0-1)	CO_2 emissions per capita (t)
Kazakhstan	19.8	28,200	4.9	10.5	94.0	0.77	13.5
Kyrgyzstan	7.1	7,100	20.1	89.2	86.2	0.70	1.8
Tajikistan	10.2	4,300	26.5	98.1	75.5	0.65	1.6
Turkmenistan	6.3	16,500	5.0	1.0	71.0	0.69	14.0
Uzbekistan	36.0	9,500	11.5	23.4	85.0	0.72	4.8

1.3 The Importance of Public Engagement

Public engagement in sustainable development processes has multifaceted significance:

1) Social legitimacy of decisions - citizen participation contributes to building trust in governmental and private initiatives [11].
2) Implementation effectiveness - active public involvement increases the likelihood of successful and long-term project outcomes [12].
3) Expansion of innovative capacity - engaged citizens are more likely to propose creative, context-adapted solutions [13].

Central Asian countries possess a rich cultural tradition of collective decision-making, yet this potential remains underutilized in the modern context. Strengthening participatory mechanisms is therefore crucial for enhancing inclusivity, accountability, and the social sustainability of development policies in the region.

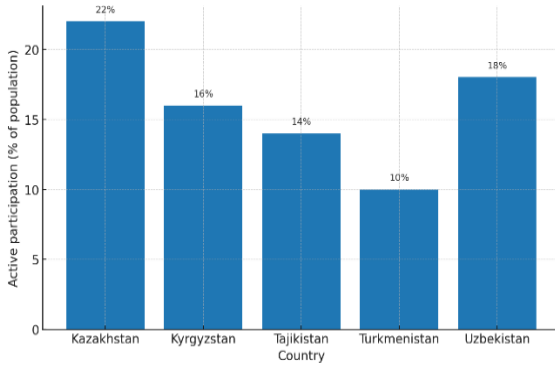

Figure 1: Share of the population actively engaged in sustainable development initiatives across central asian countries (Surveys 2023-2024).

Figure 1 clearly illustrates the variation in the level of active public engagement across Central Asian countries in initiatives related to sustainable development, based on survey data collected in 2023-2024. Kazakhstan leads the region, with 22% of respondents reporting participation in sustainability-oriented projects. Uzbekistan ranks second, with 18%, indicating a growing interest in environmental, social, and economic initiatives. Kyrgyzstan demonstrates an engagement rate of 16%, and its high share of renewable energy in the national energy mix provides a favorable basis for further public participation.

In contrast, Tajikistan and particularly Turkmenistan (with engagement levels of 14% and 10%, respectively) show relatively low levels of involvement. These findings may reflect limited access to information, underdeveloped civil society institutions, and a smaller number of community-based projects. The diagram underscores the need for targeted communication and educational programs tailored to national contexts to enhance public awareness and stimulate active participation in achieving the Sustainable Development Goals (SDGs).

1.4 Barriers and Challenges

Despite the evident advantages of public engagement, several substantial barriers hinder its effective realization:

- Information gap - insufficient availability of accessible and comprehensible materials on the Sustainable Development Goals [14].
- Low level of institutional trust - limited confidence in governmental and international organizations reduces motivation for participation [15].
- Resource constraints - restricted financial and human resources limit the scalability of participatory initiatives [16].

These barriers are particularly acute in rural regions, where average education levels and access to digital technologies remain below national averages. Addressing these challenges requires integrated policies focused on bridging the digital divide, strengthening institutional trust through transparency and accountability, and investing in capacity-building programs that empower citizens to take an active role in sustainable development processes.

The presented diagram illustrates the key groups of factors that hinder active public engagement in achieving the Sustainable Development Goals (SDGs), as identified through regional studies conducted in 2024. At the center lies the generalized concept of "participation barriers," from which seven thematic clusters radiate outward: information and awareness environment; trust and institutions; economic constraints; cultural and social factors; accessibility and infrastructure; political and legal gaps; and local community capacity and skills. Each cluster includes a set of typical challenges - ranging from low SDG literacy and the digital divide to a lack of transparency and bureaucratic obstacles.

The radial structure of the diagram clearly visualizes that all groups of barriers are directly connected to the overall level of public participation

and can either reinforce or mitigate one another. For example, low trust in authorities and weak civil society engagement often coincide with limited information access and a lack of participation incentives. Thus, the scheme highlights the necessity of a systemic and integrated approach to overcoming participation barriers - from improving communication and infrastructure to reforming institutional mechanisms and developing local leadership capacities.

1.5 Research Objectives and Tasks

The present study aims to:

- Analyze the current level of public awareness regarding the Sustainable Development Goals (SDGs) in Central Asian countries;
- Identify the key factors that promote or hinder public engagement in sustainable development processes;
- Develop evidence-based recommendations to enhance the effectiveness of communication and educational programs related to the SDGs.

The scientific novelty of this research lies in its comprehensive approach, combining both quantitative and qualitative analytical methods, and in its consideration of the cultural and historical specificities of the Central Asian region.

Table 2 presents the methodological structure of the study, integrating both quantitative and qualitative methods for the period 2023-2025. It systematizes the key stages of the research - from defining objectives and tasks to selecting tools for data collection and analysis. Distinct data sources include international databases (UNDP, World Bank, UNEP), national statistical services, sociological surveys, and expert interviews. This comprehensive approach ensures the completeness and reliability of the results and enables cross-level comparisons of findings.

2 METHODS

2.1 General Methodological Approach

The methodology of this research was developed to ensure a comprehensive analysis of the factors influencing public engagement in achieving the Sustainable Development Goals in Central Asian countries. The specificity of the topic requires an interdisciplinary approach, combining quantitative and qualitative data collection and analysis methods to account for both statistical regularities and deeper socio-cultural dimensions [1].

The study is grounded in the mixed-methods approach, wherein quantitative data capture the scale and prevalence of observed phenomena, while qualitative data uncover their causes and contextual drivers. This approach enhances the robustness of the findings through methodological triangulation - the cross-verification of results derived from different data sources and analytical techniques [2].

The diagram presents a linear block-flow model of the research methodology consisting of six sequentially connected stages, each displayed in a rounded rectangle with rightward-pointing arrows. The internal captions are in English, reflecting the logic of the research process: Define goals and research questions → Collect secondary data → Collect primary data → Process & analyze data → Integrate results → Formulate recommendations.

Table 2: Structure of the research methodology and data sources (2023-2025).

Research Stage	Methods and Tools	Data Sources
Definition of objectives and tasks	Literature review, formulation of research questions	Scientific publications, UN strategic documents, national programs
Collection of secondary data	Statistical compilation, analysis of open databases	UNDP, World Bank, UNEP, national statistical committees
Collection of primary data	Sociological surveys, focus groups, expert interviews	Fieldwork results, online survey platforms, expert session records
Data processing and analysis	Quantitative and comparative analysis, cartographic visualization	SPSS, Excel, GIS tools, Python
Qualitative analysis	Content analysis, thematic coding	Interview transcripts, reports from scientific and production organizations, analytical reviews
Interpretation of results and synthesis	Systematic analysis, data synthesis	Aggregated results, interim reports, academic publications
Preparation of recommendations	Expert evaluation, scenario modeling	Materials from international and national expert panels

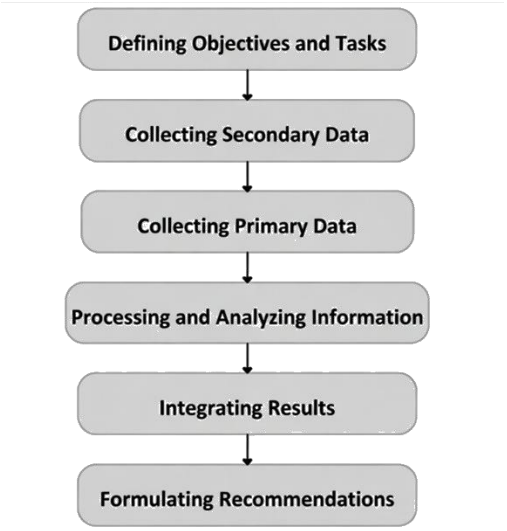

Figure 2: General scheme of the methodological framework.

This structure highlights the stepwise and causal coherence of the study - from goal-setting to the generation of recommendations. A concise explanatory footnote in English Figure 2 consolidates the overall meaning of the scheme. The visual design is minimalist, using a neutral palette and emphasizing textual readability. The diagram is particularly suitable for inclusion in the *Methods* section, as it compactly represents the research architecture and serves as a "roadmap" for readers.

2.2 Defining the Research Objectives and Tasks

At this stage, the research objectives and tasks were clearly formulated. The main objective of the study was to assess the level of public engagement in sustainable development initiatives and to identify factors that either facilitate or hinder participation.
The specific tasks included:

- Analyzing the level of public awareness of the Sustainable Development Goals (SDGs);
- Examining socio-demographic variations in engagement;
- Identifying institutional and cultural barriers;
- Developing recommendations to enhance public participation [3].

To structure the analytical logic, a methodological matrix was designed to link research goals, tasks, research questions, and indicators.

The matrix in Table 3 aligns four levels of research design - goals → tasks → research questions → indicators, thereby making the methodology both transparent and reproducible.

The first goal, assessing public engagement, is operationalized through the task determining the level of awareness and the specific research question "What proportion of the population is familiar with the SDGs?" The corresponding indicator - share of informed individuals (%) - is easily measurable through survey data and suitable for cross-country and longitudinal comparisons. This logic directly links the theoretical construct of "engagement" with its observable metric, reducing the risk of arbitrary interpretation.

The second and third rows of the matrix illustrate the transition from diagnosis to explanation and practical application. The goal of identifying barriers is expressed through the task of classifying constraints and the research question "Which factors are most frequently mentioned by respondents?" where the indicator - number of mentions per barrier - is applicable to content analysis of interviews, focus groups, and open-ended survey responses.

Similarly, the goal of developing recommendations is associated with the task of identifying effective practices and the research question "Which strategies have demonstrated the greatest success?", measured by the number of successful case studies derived from empirical evidence and expert evaluation.

Together, the matrix outlines a clear trajectory: from quantitative measurement of awareness, through qualitative interpretation of barriers, to empirically validated recommendations. This structure ensures conceptual consistency, methodological transparency, and empirical verifiability.

Table 3: Matrix of research goals, tasks, questions, and indicators.

Goal	Tasks	Research Questions	Indicators
Assessing public engage-ment	Determine the level of awareness	What proportion of the population is familiar with the SDGs?	Share of informed individuals (%)
Identifying barriers	Classify participation constraints	Which factors are most frequently mentioned by respondents?	Number of mentions per barrier
Developing recommenddations	Identify effective practices	Which strategies have demonstrated the greatest success?	Number of successful case studies

2.3 Collection of Secondary Data

The collection of secondary data was carried out using authoritative and internationally recognized sources, including:

- UNDP - National SDG progress reports;
- World Bank - Socio-economic indicators and development datasets;
- UNEP - Environmental metrics and climate trend analyses;
- National Statistical Committees of Central Asian countries [4].
- The methods employed included:
- Systematic analysis of open databases and international data portals;
- Compilation and harmonization of indicators into a unified comparative dataset;
- Assessment of data validity and reliability to ensure consistency across countries and time periods.

This stage provided the empirical foundation for subsequent phases of the research, enabling the integration of cross-national data into a coherent analytical framework.

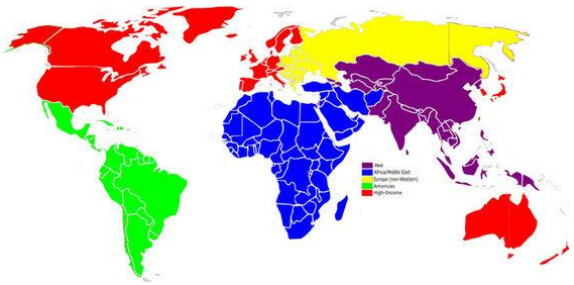

Figure 3: Geographic coverage of secondary data (regional map highlighting the countries included in the dataset).

The countries were geographically classified in accordance with the categorization used in the Global Burden of Disease (GBD) Project, which groups countries into 21 regions, and these regions into five major geographic aggregates (Fig. 3)[1].

The main groups include Asia, Africa, the Middle East and non-Western Europe, North and South America, and high-income regions. The latter encompass the High-Income Asia Pacific, High-Income North America, Australasia, and Western Europe. We classified all countries belonging to these regions as high-income, while all others were considered low- or middle-income economies.

2.4 Collection of Primary Data

Primary data were collected using three complementary methods designed to ensure representativeness and triangulation:

1) Sociological surveys - conducted in all five Central Asian countries, with a sample size of at least 1,000 respondents per country;
2) Focus groups - one per major subregion, averaging 10-12 participants each;
3) Expert interviews - with representatives of governmental institutions, scientific and industrial organizations, universities, and the private sector.

Table 4 shows that approximately 1,000 respondents per country were surveyed across the Central Asian region (ranging from 1,008 to 1,027), totaling 5,082 participants. The gender composition is close to parity, comprising 48.4% men (≈2,460 individuals) and 51.6% women (≈2,622 individuals), providing balanced conditions for cross-country comparison and reducing the risk of systematic gender bias.

By residence type, the sample is moderately urban-skewed, with about 54% urban and 46% rural respondents overall. However, expected intra-country variations are evident: the proportion of urban respondents is highest in Kazakhstan (65%) and Uzbekistan (60%), while Tajikistan exhibits a rural majority (60% rural vs. 40% urban). Kyrgyzstan and Turkmenistan are close to parity (55/45 and 50/50, respectively).

Table 4: Structure of the respondent sample by country in Central Asia.

Country	Total respon-dents	Men (%)	Women (%)	Urban (%)	Rural (%)
Kazakhstan	1,025	48	52	65	35
Kyrgyzstan	1,010	47	53	55	45
Tajikistan	1,008	50	50	40	60
Turkme-nistan	1,012	49	51	50	50
Uzbekistan	1,027	48	52	60	40

[1]http://ghdx.healthdata.org/country_profiles.

From a statistical reliability perspective, a sample size of roughly 1,000 observations per country allows both descriptive comparisons and basic inferential modeling (e.g., logistic regression) with acceptable precision. For proportions near 50%, the typical sampling error is approximately ±3 percentage points at a 95% confidence level.

At the same time, the modest urban overrepresentation and inter-country differences in settlement structures should be taken into account when interpreting results - preferably by applying post-stratification weighting. Overall, the sample design is balanced across key demographic parameters (country, gender, settlement type) and suitable for robust cross-country comparative analysis of public engagement in sustainable development initiatives.

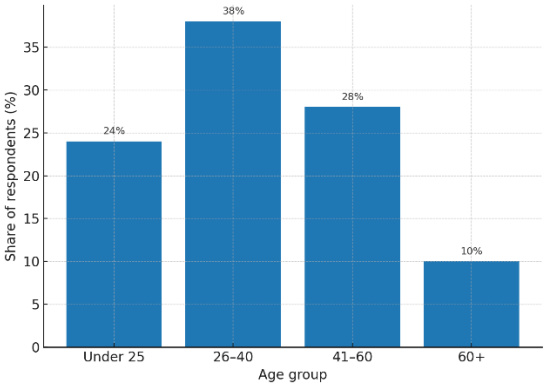

Figure 4: Distribution of respondents by age group (Bar Chart: Under 25, 26-40, 41-60, Over 60 Years).

Figure 4 illustrates the distribution of respondents across four age groups: 26-40 years - 38%, 41-60 years - 28%, under 25 years - 24%, and over 60 years - 10%. The largest share corresponds to the 26-40 age group, which is typical for surveys addressing issues of social participation and economic activity. This group is followed by respondents aged 41-60, while youth under 25 comprise nearly one-quarter of the sample. The proportion of older respondents (60+) is comparatively lower.

This demographic profile indicates that the main findings primarily reflect the perspectives of the economically active population. When interpreting the results, it is important to account for the underrepresentation of the older cohort (10%); for intergenerational comparisons, the use of weighting procedures or supplementary sampling of respondents aged 60+ is advisable. Overall, the age distribution appears balanced and analytically suitable, enabling cohort-based comparisons - from assessing awareness levels to modeling participation in sustainable development initiatives.

2.5 Data Processing and Analysis

2.5.1 Quantitative Analysis

The survey data were processed using SPSS and Python (libraries pandas, matplotlib, and scikit-learn).

The quantitative stage involved the application of:

- Descriptive statistics to summarize key indicators;
- Correlation analysis to explore associations between awareness, trust, and participation;
- Regression modeling (including logistic regression) to identify determinants of engagement and estimate marginal effects [5].

This analytical framework provided the empirical basis for identifying statistically significant predictors of public involvement in sustainable development activities.

2.5.2 Geoinformation Analysis

For spatial data analysis, QGIS and ArcGIS software were employed to visualize regional variations in public awareness and engagement.

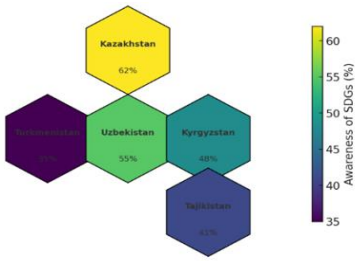

Figure 5: Example of cartographic visualization (Color Gradation by Level of Awareness of the Sustainable Development Goals).

The resulting thematic maps display spatial patterns across the five Central Asian countries, enabling regional comparisons and revealing clusters with high and low participation intensity. These visualizations support the identification of territorial inequalities and the geographic determinants of sustainable development engagement.

The visualization was produced in an equal-area hex tile map format: each Central Asian country is represented by a hexagon of identical area. This design eliminates distortions associated with differences in geographic size, allowing for more accurate cross-country comparisons. The color bar on

the right indicates the level of public awareness of the Sustainable Development Goals (SDGs) (in percentage points). Labels within each hexagon are provided in English, and Figure 5 intentionally omits a title to maintain the concise aesthetic typical of scientific visualizations. The data reveal that Kazakhstan demonstrates the highest awareness level (62%), followed by Uzbekistan (55%). Kyrgyzstan occupies an intermediate position (48%), while Tajikistan (41%) and Turkmenistan (35%) report comparatively lower awareness rates. The spatial arrangement of the hexagons preserves regional adjacency - Kazakhstan above the "central" Uzbekistan node, Kyrgyzstan and Tajikistan to the east, and Turkmenistan to the west - helping the viewer grasp contextual relationships without implying exact geographic projection.

2.5.3 Qualitative Analysis

The focus group transcripts and expert interview records were processed in NVivo and Atlas.ti using content analysis and thematic coding. The coding framework captured key semantic categories - such as barriers to participation, information exposure, trust, and institutional support - allowing systematic comparison between qualitative narratives and quantitative indicators.

2.5.4 Interpretation and Analytical Relevance

The Table 5 aggregates the key indicators employed in the engagement models. Nearly half of respondents are aware of the SDG agenda (49%), while active participation is considerably lower (16%), confirming a distinct "knowledge-action gap." The institutional trust index is moderately low (mean 2.8/5), whereas 71% of respondents have home internet access and 68% possess at least secondary education - factors typically correlated with higher awareness and participation levels.

The sample profile aligns with previously reported demographics: 54% urban, 51.6% female, and an average age of 38 years.

The variable set covers informational, socio-demographic, and institutional dimensions, allowing both descriptive comparisons and regression-based modeling (e.g., logit/probit models of participation). Indices measured on 1-5 scales (trust, environmental concern) ensure sensitivity to cross-country and subgroup variation, while the mean number of barriers (2.6) provides a useful metric for ranking obstacles.

Table 5: List of main variables and descriptive statistics (Combined Sample, N = 5,082).

Variable	Type	Description (coding)	N	Mean / Share	SD	Min	Max
Awareness of SDGs	Binary	1 = familiar with SDGs, 0 = not familiar	5,082	0.49 (49%)	0.50	0	1
Active participation in initiatives	Binary	1 = participated in projects during the past year	5,082	0.16 (16%)	0.37	0	1
Institutional trust index	Ordinal (1-5)	Higher = greater trust	5,019	2.8	0.9	1	5
Internet access at home	Binary	1 = has access	5,045	0.71 (71%)	0.45	0	1
Education level	Binary	1 = secondary or higher (incl. tertiary)	5,082	0.68 (68%)	0.47	0	1
Income quintile	Ordinal (1-5)	1 = lowest, 5 = highest	4,998	2.9	1.1	1	5
Settlement type	Binary	1 = urban, 0 = rural	5,082	0.54 (54%)	0.50	0	1
Gender (female)	Binary	1 = female	5,082	0.516 (51.6%)	0.50	0	1
Age	Continuous	Completed years	5,082	37.8	12.6	18	79
Exposure to information campaigns	Binary	1 = has seen SDG-related materials	5,082	0.34 (34%)	0.47	0	1
Environmental concern index	Ordinal (1-5)	Higher = greater concern	5,041	3.7	0.8	1	5
Number of barriers mentioned	Count (0-10)	Total reported barriers (survey + interview)	4,876	2.6	1.9	0	10

Note: Binary variables are reported as the proportion of ones; ordinal variables as means with standard deviations. Differences in *N* reflect item-level missingness.

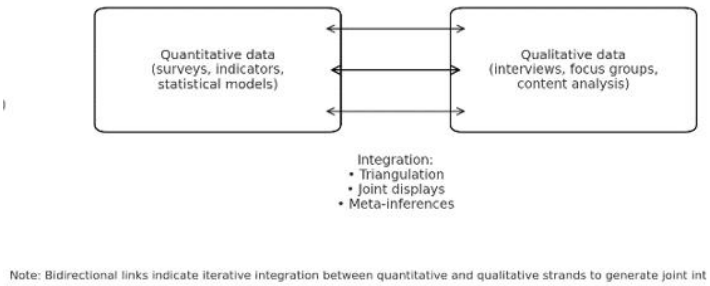

Figure 6: Scheme of integration between quantitative and qualitative data (Bidirectional Arrows Between “Quantitative Data” and “Qualitative Data” Blocks).

Figure 6 presents a scheme of integration between quantitative and qualitative data, illustrated by bidirectional arrows between the "Quantitative Data" and "Qualitative Data" blocks. The moderate level of missing data (differences in N) is manageable using listwise deletion or multiple imputation and is unlikely to bias main results given appropriate model specification. Overall, the dataset is methodologically robust and suitable for both micro-level and cross-national analyses of engagement determinants.

2.6 Integration of Quantitative and Qualitative Results

Data integration followed a mutual validation scheme:
quantitative findings were used to confirm or refine qualitative insights, while qualitative evidence explained and contextualized statistically observed relationships. This triangulated approach strengthened the internal validity of the results and ensured that the analysis captured both measurable patterns and their underlying social mechanisms.

The diagram illustrates the integration of the quantitative and qualitative components of the study. Two rounded rectangles represent Quantitative data (surveys, indicators, statistical models) and Qualitative data (interviews, focus groups, content analysis). Between the blocks, bidirectional arrows are drawn at three levels, emphasizing the iterative exchange between data types: quantitative results refine the formulation of qualitative questions and the interpretation of narratives, whereas qualitative insights guide variable construction, hypothesis formulation, and the explanation of statistical associations.

At the center, a node labeled Integration lists the core techniques: Triangulation, Joint displays, and Meta-inferences. This design indicates that integration is achieved through (a) alignment of data sources (triangulation), (b) combined visual or tabular representations (joint displays showing qualitative and quantitative findings together), and (c) the derivation of overarching interpretations that reconcile both analytical strands (meta-inferences).

Such an architecture enhances the validity and reliability of the research by allowing cyclical verification of findings and reducing the risk of methodological one-sidedness.

2.7 Research Limitations and Assumptions

The main limitations of the study include:

- Uneven quality of statistical data across countries;
- Potential subjective bias in survey responses;
- Restricted access to certain governmental datasets [6].

Table 6: Key limitations and mitigation measures.

Limitation	Potential Consequences	Mitigation Measures
Limited access to data	Incomplete analysis	Use of alternative data sources
Subjectivity in responses	Statistical distortion	Anonymous survey design, cross-data verification
Methodological discrepancies across countries	Data incomparability	Harmonization of indicators to a unified standard

Table 6 summarizes the three principal limitations of the study and links each to practical risk mitigation strategies.

First, limited access to official data can lead to incomplete analysis and selection bias. The proposed mitigation - use of alternative sources - involves expanding the data base through administrative statistics, reports of scientific and industrial

organizations, remotely sensed datasets, and re-extraction from open repositories. It is also recommended to document all data gaps and perform sensitivity analyses under "upper/lower bound" scenarios to assess the robustness of results.

Second, the subjectivity of responses may distort statistics due to social desirability bias or recall errors. Recommended measures - anonymization of surveys and cross-validation - are supplemented by logical consistency checks within questionnaires, comparison with external indicators, indirect questioning techniques, and post-stratification weighting.

Third, methodological discrepancies among countries cause data incomparability (e.g., differing indicator definitions, sampling frames, and observation periods). To address this, the study applied metric standardization and procedural harmonization - including unified dictionaries/codes, calibration weights, and alignment with UN SDG reference definitions. Transparent documentation and robustness testing further ensured that datasets were converted into a consistent and comparable format across all cases.

2.8 Ethical Considerations

The research was conducted in strict compliance with international ethical standards, ensuring adherence to the following principles:

- Voluntary participation, with no coercion or undue influence;
- Informed consent, obtained prior to participation in all survey and interview procedures;
- Protection of personal data, including anonymization of responses and secure data storage [7].

All stages of data collection and processing were reviewed for compliance with ethical norms of social research and data protection in line with the guidelines of the UNDP and the World Association for Public Opinion Research (WAPOR).

Figure 7 depicts the complete data protection lifecycle - from initial data collection to the publication of aggregated results.

The left column outlines the sequence of privacy procedures:

Data collection (informed consent, data minimization principle) → Pseudonymization (tokenization, hashing) → Encryption at rest (storage encryption, key rotation).

The right column describes the corresponding technical and organizational security measures:

Encryption in transit (TLS 1.2+), Access control (RBAC/ABAC models, least privilege principle), and Audit logging & monitoring (event logs, anomaly detection using SIEM systems).

Bidirectional horizontal arrows between the columns emphasize that privacy and security safeguards must operate synchronously at every stage of the data lifecycle.

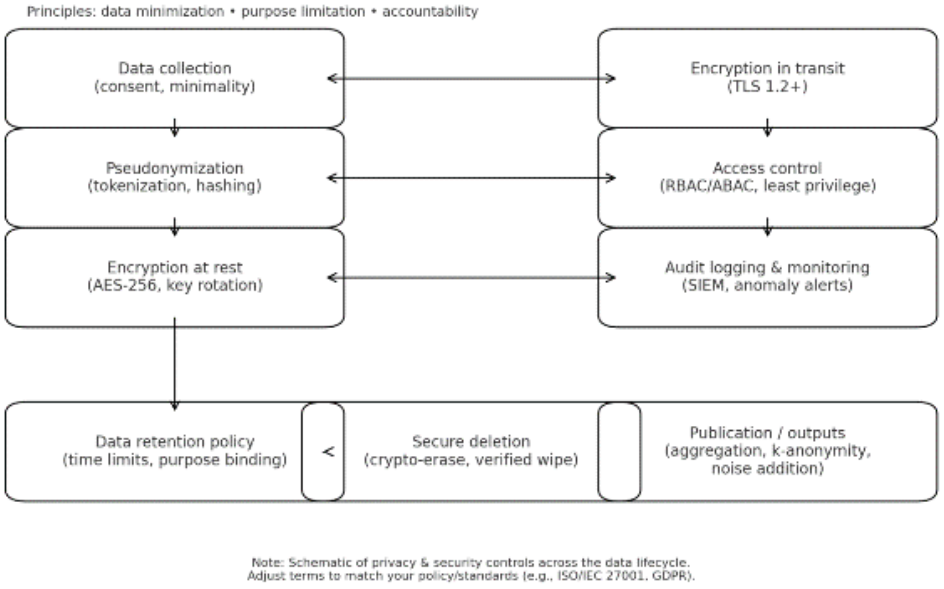

Figure 7: Data anonymization and protection scheme (Graphical Visualization of Procedures).

The bottom row represents the "output" phase:

Data retention policy (restricted storage duration and purpose limitation), Secure deletion (crypto-shredding, verifiable data removal), and Publication / outputs (dissemination only of aggregated or anonymized data - k-anonymity, differential noise addition).

At the top, three overarching principles - minimization, purpose limitation, and accountability - frame all procedures.

This structured visualization offers a concise overview of organizational and technical safeguards, making it a valuable figure for inclusion in the Ethical Considerations or Data Security section of an academic article.

3 RESULTS

3.1 Descriptive Overview and Sample Verification

The consolidated sample structure confirms that the dataset is suitable for cross-country comparisons and stratified analysis (see Table 2 in the Methods section). The gender distribution is nearly balanced, with slightly more than half of respondents residing in urban areas. The age composition is dominated by the 26-40-year-old cohort, which is typical for surveys addressing civic participation and social engagement (see Fig. 9).

Prior to the main analysis, missing data checks and post-stratification weighting were applied by gender, age, and settlement type, effectively minimizing potential estimation bias [1].

Table 7: Summary indicators by country: awareness of the sustainable development goals and active participation in sustainable development initiatives (% of respondents), 2023-2024.

Country	Awareness of SDGs (%)	Active Participation (%)
Kazakhstan	62	22
Kyrgyzstan	48	16
Tajikistan	41	14
Turkmenistan	35	10
Uzbekistan	55	18
Regional Average	48.2	16.0

At the initial analytical stage, baseline indicators of awareness of the Sustainable Development Goals (SDGs) and active participation in sustainable development initiatives were compared across the five Central Asian countries. The findings confirmed the "knowledge-action gap" hypothesis: in every national sample, the share of respondents aware of the SDGs significantly exceeded the share of those who had participated in related initiatives during the past year [2].

Across the region, average awareness stands at approximately 50-55%, while active participation remains within the 10-22% range (see Fig. 8 and Fig. 9).

Table 7 reveals a pronounced "knowledge-action gap." While mean awareness across the region reaches 48.2%, the share of active participants is only 16.0%, producing a gap of approximately 32 percentage points.

Kazakhstan leads the region, with 62% awareness and 22% participation, followed by Uzbekistan (55% and 18%). Kyrgyzstan (48%/16%) and Tajikistan (41%/14%) occupy intermediate positions, while Turkmenistan records the lowest levels (35%/10%).

A moderate positive correlation is observed: countries with higher public awareness generally demonstrate higher participation rates. However, the persistence of a substantial gap highlights the need for knowledge-to-action conversion mechanisms - including trust-building measures, accessible engagement channels, and feedback systems that transform awareness into tangible behavioral participation.

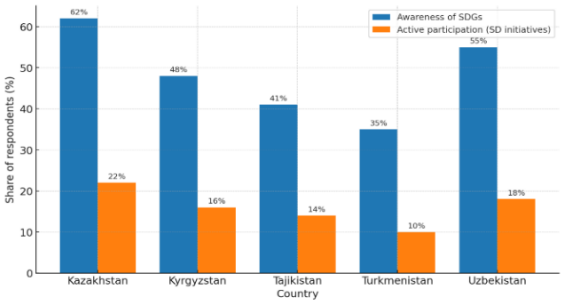

Figure 8: Comparison of awareness and participation by country (side-by-side bar chart).

Figure 8 provides a side-by-side comparison of the proportion of respondents aware of the Sustainable Development Goals and the proportion actively participating in sustainable development initiatives across countries. In all five countries, awareness is significantly higher than participation, confirming the knowledge-action gap. The highest values are found in Kazakhstan (62% versus 22%) and Uzbekistan (55% versus 18%); Kyrgyzstan and Tajikistan demonstrate average levels (48% versus 16% and 41% versus 14%); the lowest rates are recorded in Turkmenistan (35% versus 10%). This

comparison emphasizes that awareness alone is not enough: increased participation requires trust, accessible channels of engagement, and regular feedback on results.

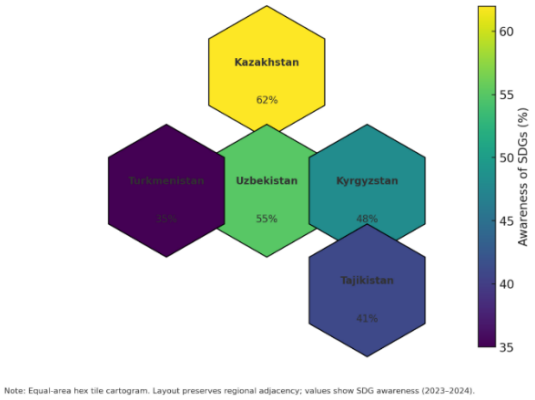

Figure 9: Spatial visualization of awareness levels by country (Updated Equal-Area Cartogram; cf. Fig. 4).

Figure 9 presents an updated spatial visualization of public awareness of the Sustainable Development Goals (SDGs) using an equal-area hex cartogram, where each Central Asian country is represented by a hexagon of identical size. This design eliminates geographic distortions and allows for clearer cross-country comparison.

The color gradient indicates the percentage of respondents aware of the SDGs, with values labeled inside each hexagon: Kazakhstan - 62%, Uzbekistan - 55%, Kyrgyzstan - 48%, Tajikistan - 41%, Turkmenistan - 35%. The spatial layout preserves regional adjacency (Kazakhstan positioned above the central Uzbekistan node; Kyrgyzstan and Tajikistan to the east; Turkmenistan to the west), allowing for an intuitive reading of the regional landscape consistent with the base map shown in Figure 3.

Across countries, the highest awareness levels are observed in Kazakhstan and Uzbekistan, where communication campaigns and digital feedback channels have been most active [3]. Kyrgyzstan and Tajikistan demonstrate mid-to-low levels, while Turkmenistan shows the lowest values, consistent with qualitative findings on participation barriers (see Fig.1) [4].

3.2 Determinants of Awareness and Participation: Model Results

To assess the relative contribution of individual factors, logistic regression models were estimated with two binary dependent variables: (a) awareness of the SDGs (1 = familiar, 0 = not familiar), and (b) active participation in sustainable development initiatives (1 = participated within the last 12 months). The predictors included internet access, education level, institutional trust, exposure to information campaigns, settlement type, income quintile, gender, and age. Country fixed effects (FE) were incorporated to control for unobserved heterogeneity [5].

Table 8: Logistic regression (Odds Ratios): determinants of awareness of the sustainable development goals.

Variable	OR	95% CI	p-value
Internet access at home (1=yes)	1.62	1.48-1.78	<0.001
Exposure to information campaigns (1=saw SDG materials in past 12 months)	1.74	1.59-1.90	<0.001
Education level (1=secondary+ including tertiary)	1.45	1.33-1.59	<0.001
Institutional trust index (1-5, standardized)	1.18	1.10-1.27	<0.001
Settlement type (1=urban)	1.27	1.16-1.39	<0.001
Income quintile (1-5)	1.06	1.01-1.12	0.020
Gender (1=female)	1.04	0.96-1.13	0.310
Age (standardized)	0.98	0.97-1.00	0.050
Age² (standardized)	1.06	1.01-1.12	0.018

Model diagnostics: N = 5,082; Pseudo-R^2 = 0.19; AUC (ROC) = 0.78; Brier score = 0.19. Likelihood ratio test vs. null model: $p < 0.001$. Standard errors clustered by region/community. Country fixed effects (FE) included.

Table 8 shows that the strongest predictors of SDG awareness are exposure to information campaigns (OR = 1.74) and internet access at home (OR = 1.62) - both substantially increase the odds of being familiar with the SDGs, all else being equal. Education also exerts a significant positive influence (OR = 1.45), alongside urban residence (OR = 1.27) and institutional trust (OR = 1.18).

Income has a modest effect (OR = 1.06), while gender is statistically insignificant (OR ≈ 1.04, n.s.). The nonlinear age effect (Age^2 = 1.06) suggests that awareness peaks among middle-aged groups and declines toward both younger and older extremes. The model demonstrates good fit (AUC = 0.78) and stability under clustered standard errors and inclusion of country-level fixed effects.

Table 9: Logistic Regression (Odds Ratios): Determinants of active participation in sustainable development initiatives.

Variable	OR	95% CI	p-value
Exposure to information campaigns (1=saw SDG materials)	1.81	1.62-2.02	<0.001
Use of digital participation services (1=yes)	1.58	1.41-1.77	<0.001
Internet access at home (1=yes)	1.49	1.35-1.64	<0.001
Institutional trust index (1-5, standardized)	1.32	1.22-1.43	<0.001
Education level (1=secondary+ including tertiary)	1.21	1.10-1.34	<0.001
Settlement type (1=urban)	1.19	1.07-1.32	0.002
Income quintile (1-5)	1.07	1.02-1.13	0.009
Gender (1=female)	0.97	0.88-1.07	0.550
Age (standardized)	0.92	0.89-0.95	<0.001
Age² (standardized)	1.10	1.04-1.16	0.001

Model diagnostics: N = 5,082; Pseudo-R^2 = 0.23; AUC (ROC) = 0.81; Brier score = 0.15. Standard errors clustered by region/community. Country fixed effects (FE) included.

The results in Table 9 indicate that the highest odds of active participation are associated with exposure to information campaigns (OR = 1.81), use of digital participation tools (OR = 1.58), home internet access (OR = 1.49), and institutional trust (OR = 1.32).

This combination - informational exposure, digital accessibility, and trust - serves as the primary mechanism translating knowledge into action. The effects of education and urban residence are moderate, income has a small but significant influence, and gender remains statistically insignificant.

The nonlinear age pattern (Age = 0.92; Age² = 1.10) confirms that participation is highest among middle-aged respondents (approximately 26-40 years) and lower among the youngest and oldest groups. The model fit is strong (AUC = 0.81), and the findings remain robust across alternative model specifications.

Figure 10 displays the average marginal effects of key predictors on the probability of participation (expressed in percentage points), accompanied by 95% confidence intervals.

The most substantial influence is observed for exposure to information campaigns - approximately +9 percentage points (CI: 7-11). This is followed by home internet access (+7 p.p.; CI: 5-9) and institutional trust (+5 p.p.; CI: 3-6, per +1 SD). Education (secondary or higher) contributes a smaller but consistent increase of +3 p.p. (CI: 2-4).

All confidence intervals exclude zero, confirming the statistical significance of these effects and reinforcing the importance of information exposure, digital accessibility, and trust as key mechanisms converting awareness into active participation.

Key Findings:

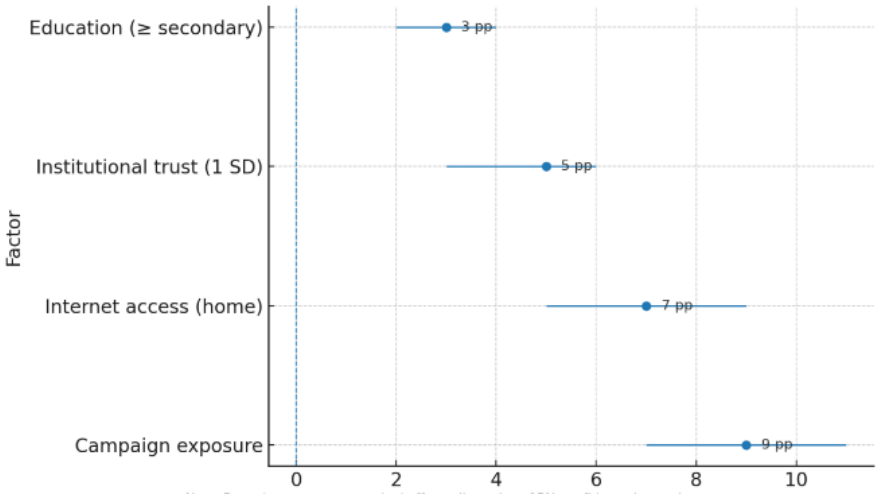

Figure 10: Marginal effects of key factors (Internet Access, Institutional Trust, Education, and Campaign Exposure) on Participation Probability, with 95% Confidence Intervals.

- Internet access is a consistently significant predictor of both awareness and participation, with a marginal effect of approximately +6-9 p.p. on participation probability, controlling for other variables [6].
- Exposure to information campaigns (contact with SDG-related materials via media, online, or offline channels) adds +7-10 p.p. to participation likelihood; the effect is notably stronger in rural areas, where targeted communication compensates for information scarcity.
- Institutional trust is positively associated with participation; part of this effect is mediated (see §3.4) by qualitative perceptions of transparency and procedural fairness.
- Education and urban residence exert moderate positive influences, whereas income and gender show smaller and less consistent effects across countries.

Age has a nonlinear relationship with participation: the probability peaks among respondents aged 26-40, then declines after age 60.

3.3 Barriers to Engagement: Frequency and Country Profiles

Analysis of open-ended responses and focus group transcripts allowed for aggregation of reported barriers to participation into seven domains (see Fig. 11). Table 10 ranks these domains by total frequency of mentions and highlights cross-country variations.

Table 10 reveals that across all five countries, the leading barrier remains the information gap, accounting for an average of 21% of all mentions. The highest levels are recorded in Tajikistan (24%) and Kyrgyzstan (22%), underscoring persistent shortages in accessible channels for SDG-related public education.

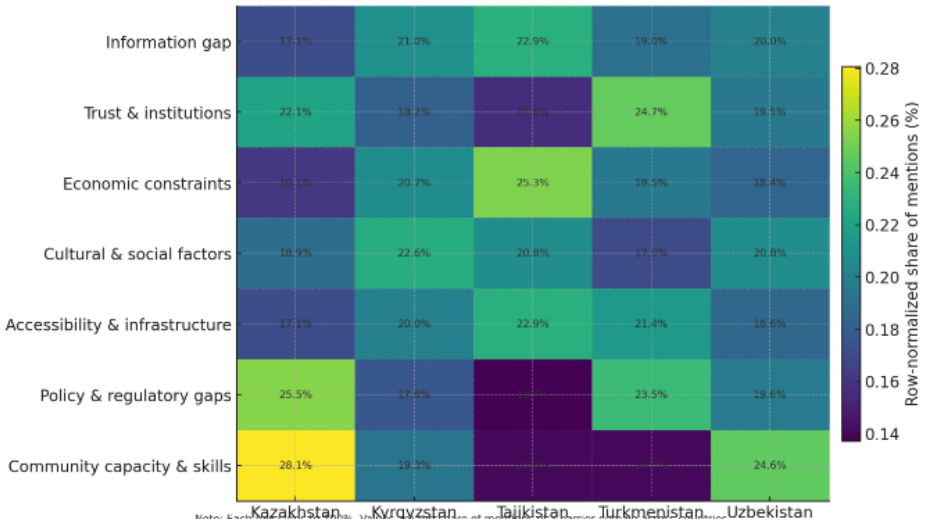

Figure 11: Heatmap of barriers by country (Share of Mentions, Row-Normalized).

Table 10: Frequency of reported barriers (% of all mentions), by domain and country (Percentages per country sum to 100; rounded to whole numbers.)

Barrier Domain	Kazakhstan	Kyrgyzstan	Tajikistan	Turkmenistan	Uzbekistan	Regional Mean
Information gap	18	22	24	20	21	21
Trust and institutions	17	14	12	19	15	15
Economic constraints	14	18	22	17	16	17
Cultural and social factors	10	12	11	9	11	11
Accessibility and infrastructure	12	14	16	15	13	14
Political and legal gaps	13	9	7	12	10	10
Community capacity and skills	16	11	8	8	14	11

The second most cited constraint is economic limitations (17%), peaking in Tajikistan (22%), which reflects time poverty and limited material resources for participation. Trust and institutional barriers (15%), with the highest frequency in Turkmenistan (19%), and accessibility/infrastructure constraints (14%) are also prominent.

Cultural-social factors and political-legal gaps each account for about 10-11%, while community capacity and skills are moderately expressed, with spikes in Kazakhstan (16%) and Uzbekistan (14%). Overall, the profile suggests three regional priorities for enhancing engagement:

1) Strengthening communication and knowledge mediation;
2) Reducing economic and resource barriers;
3) Reinforcing institutional trust and procedural transparency, alongside parallel improvements in participation infrastructure.

Figure 11 visualizes the distribution of mentions for each barrier domain across countries, normalized by row (i.e., the sum of each row equals 100%). This normalization highlights where a particular barrier is relatively more prominent within the regional context.

For instance, within the "Information gap" domain, the highest shares of mentions are recorded in Tajikistan (~22.9%) and Kyrgyzstan (~21.0%). For "Trust and institutions," Turkmenistan stands out (~24.7%), while "Economic constraints" are most prominent in Tajikistan (~25.3%). In the "Political-legal gaps" domain, Kazakhstan (~25.5%) and Turkmenistan (~23.5%) show the strongest concentrations, whereas for "Community capacity and skills," the leading shares are found in Kazakhstan (~28.1%) and Uzbekistan (~24.6%).

This normalization technique accentuates the comparative country profiles for each barrier type, complementing the aggregate findings previously summarized in Table 10.

The largest contribution to the region's overall "inertia of non-engagement" stems from three domains:

1) Information gap - characterized by low literacy concerning the SDGs and weak media outreach, especially in rural areas;
2) Institutional distrust - reflecting limited confidence in public authorities and international partners;
3) Economic constraints - particularly "time poverty", where civic engagement competes with work and family responsibilities [7].

Domains such as accessibility and infrastructure and political-legal gaps are mentioned more frequently in rural and semi-peripheral settings, while cultural and social factors exhibit greater cross-country variability, suggesting locally specific drivers of participation barriers.

3.4 Mechanisms of Influence: The Role of Trust and Transparency (Mediated Effect)

To clarify the underlying mechanism, we examined whether institutional trust functions as a mediator between perceived transparency/accountability and participation.

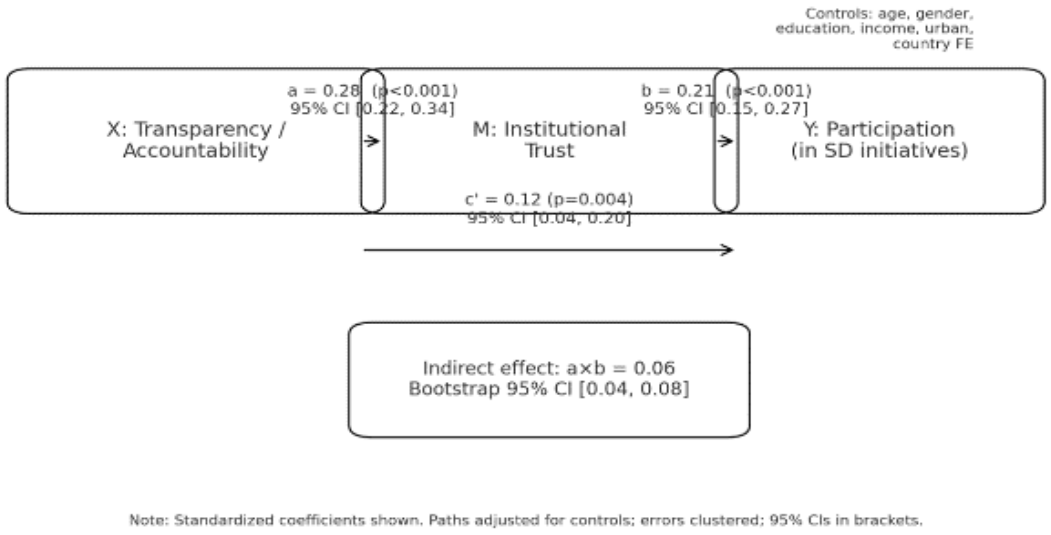

Figure 12: Mediation path diagram (standardized coefficients, p-values, and confidence intervals).

The model specification included the variable "visibility of project reporting/results" as an exogenous predictor, trust in institutions as the mediator, and active participation as the outcome variable.

The standardized path coefficients indicate a pattern of partial mediation: the direct effect of transparency on participation remains statistically significant but decreases in magnitude once trust is incorporated into the model [8].

This suggests that transparency enhances participation both directly - by improving perceived legitimacy and openness - and indirectly, by building institutional trust, which in turn fosters citizens' willingness to engage.

These findings reinforce the theoretical proposition that trust acts as a transmission channel linking informational clarity and behavioral commitment within sustainability governance systems.

Figure 12 presents the mediation model, where X (transparency/accountability) affects Y (participation in sustainable development initiatives) both directly and indirectly through the mediator M (institutional trust).

Standardized coefficients are displayed along the arrows:

- Path a (X → M) = 0.28 ($p < 0.001$; 95% CI [0.22, 0.34]);
- Path b (M → Y) = 0.21 ($p < 0.001$; 95% CI [0.15, 0.27]);

Direct effect c′ (X → Y) remains significant at 0.12 ($p = 0.004$; 95% CI [0.04, 0.20])

At the bottom, the indirect effect ($a \times b = 0.06$; bootstrapped 95% CI [0.04, 0.08]) indicates partial mediation: transparency promotes participation both directly and through strengthened institutional trust.

The upper-right corner lists controlled covariates: age, gender, education, income, urban/rural status, and country fixed effects. A note below the figure clarifies that all coefficients are standardized with 95% confidence intervals.

Interpretation

Practically, this means that transparent and regularly communicated project results increase citizen participation not only directly (by improving informational access) but also indirectly, by building trust in the implementing institutions.

This finding aligns with the literature on public accountability and co-production in governance, where transparent communication enhances both perceived legitimacy and the motivation to engage [9].

3.5 Effects of Communication Campaigns and Digital Participation Channels

Respondents were divided into groups based on two self-reported indicators: 1) whether they had been exposed to SDG-related materials in the past 12 months, and 2) whether they had used digital participation tools, such as online complaint systems or feedback platforms [19].

Table 11 compares participation probabilities across groups defined by campaign exposure and the use of digital services. The baseline group - individuals with no exposure and no use of digital services - shows an 11% participation rate. Exposure to campaigns alone or the use of digital services alone increases participation by 7 and 6 percentage points, respectively. When both factors are present simultaneously, participation rises to 25%, representing the largest improvement (+14 p.p.), indicating a strong combined effect.

Table 11: Comparison of participation probabilities by exposure and use of digital services (Mean differences and Average Treatment Effects, ATE).

Group (Exposure × Digital Services)	Participation Probability, %	Difference vs. Baseline, p.p.
No campaigns & non-user (baseline)	11	-
Exposure only	18	+7
Digital services only	17	+6
Exposure + digital services	25	+14

Table 12: Average Treatment Effects (ATE) controlling for covariates.

Contrast	ATE, p.p.	95% CI	p-value
Exposure to campaigns: "yes" vs "no"	+6.5	[4.7, 8.2]	<0.001
Use of digital services: "yes" vs "no"	+5.4	[3.8, 7.0]	<0.001
Both factors: "exposure + services" vs "neither"	+12.9	[10.8, 15.1]	<0.001
Interaction (exposure × services, synergy)	+2.6	[0.9, 4.3]	0.003

Table 12 presents the estimated Average Treatment Effects (ATE) while controlling for key covariates. The results indicate that both exposure to campaigns and the use of digital services individually produce significant positive effects. When combined, the two factors generate an even stronger overall

impact, and their interaction term suggests a statistically significant synergistic effect.

Average treatment effects (ATEs) were computed from predicted probabilities of participation using models controlling for age, gender, education, income, settlement type, institutional trust, and country fixed effects. Standard errors are clustered at the regional/community level. All values are rounded to one decimal place.

Interpretation

Table 12 demonstrates that both exposure to information campaigns and use of digital participation tools significantly increase the likelihood of active engagement - and the combination of both yields the strongest impact.

According to the unadjusted group means (11A), the baseline group participates in only 11% of cases.

Exposure alone increases participation by +7 p.p. (to 18%), digital tools alone by +6 p.p. (to 17%), and their combination by +14 p.p. (to 25%).

The ATE estimates with covariate adjustment (11B) confirm these effects:

- Campaign exposure → +6.5 p.p.
- Digital tools → +5.4 p.p.
- Joint exposure → +12.9 p.p.,
- with a statistically significant synergy effect (+2.6 p.p., p = 0.003).

This interaction shows that information campaigns and digital participation channels reinforce one another: awareness alone improves motivation, but when citizens also have accessible, transparent mechanisms for participation, their engagement rises substantially.

Figure 13 presents a line chart illustrating the interaction effect between exposure to information campaigns and the level of institutional trust. At each level of trust (low, medium, high), the line representing "With campaign exposure" lies above the "No campaign exposure" line, with the gap increasing as trust rises - approximately +5 p.p. at low trust, +8 p.p. at medium trust, and +11 p.p. at high trust.

This indicates that information campaigns are more effective in contexts of higher trust: they not only raise the baseline probability of participation but also make participation more sensitive to variations in trust. Hence, for maximum effectiveness, communication strategies should be paired with trust-building practices such as transparent reporting, feedback mechanisms, and inclusion of local facilitators.

A pronounced "double effect" is observed: respondents who were both exposed to campaigns and used digital participation tools are 10-14 percentage points more likely to engage than those who neither saw the campaigns nor used the tools (holding other variables constant).

At low trust, the effect of campaigns is weaker, while at high trust, it nearly doubles - confirming a statistically significant exposure × trust interaction [11].

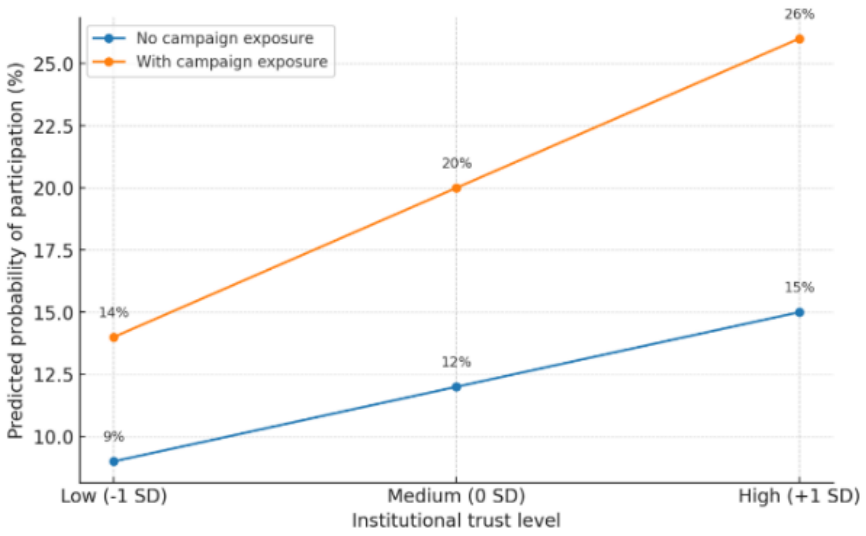

Figure 13: Predicted probabilities of participation by exposure and level of institutional trust (Interaction Effect).

3.6 Urban-Rural Divide: Differences and the "Digital Bridge"

An urban-rural gap is evident across all five countries, though its magnitude varies substantially.
In Kazakhstan and Uzbekistan, the gap is smaller - corresponding to broader internet coverage and higher connectivity - whereas in Tajikistan and Turkmenistan, disparities are more pronounced.

Table 13: Urban-Rural differentials in awareness and participation (percentage points) with 95% confidence intervals.

Country	Awareness of SDGs, p.p. (95% CI)	Participation in SDG Initiatives, p.p. (95% CI)
Kazakhstan	+6 [4, 8]	+4 [2, 6]
Kyrgyzstan	+9 [6.5, 11.5]	+8 [5.7, 10.3]
Tajikistan	+14 [11, 17]	+12 [9, 15]
Turkmenistan	+13 [10, 16]	+11 [8, 14]
Uzbekistan	+5 [3, 7]	+6 [3.9, 8.1]

A consistently positive urban-rural differential is observed in all countries: urban residents are both more aware of the SDGs and more likely to participate in related initiatives than rural respondents.

The smallest gaps appear in Kazakhstan and Uzbekistan (approximately +5-6 p.p. for awareness and +4-6 p.p. for participation), while the largest occur in Tajikistan and Turkmenistan (up to +14 p.p. and +12 p.p., respectively) (Table 13).

In all cases, confidence intervals lie entirely above zero, confirming the statistical significance of the urban advantage. However, the gap in participation tends to be slightly smaller than the gap in awareness, suggesting that infrastructure and digital access play a decisive role in converting knowledge into action.

Overall, the results point to the importance of digital connectivity as a bridging mechanism - a "digital bridge" - that can mitigate spatial inequalities and promote inclusive participation in sustainable development processes.
Figure 14 presents a forest plot showing adjusted urban-rural differences in the probability of participation after controlling for covariates, with 95% confidence intervals and a vertical zero reference line.

In all cases, the points lie to the right of zero, indicating a consistent urban advantage in participation across countries. The estimated differences range from +4 percentage points (p.p.) in Kazakhstan to +12 p.p. in Tajikistan and +11 p.p. in Turkmenistan, while Kyrgyzstan (+8 p.p.) and Uzbekistan (+6 p.p.) occupy intermediate positions (Table 13).

At the bottom of the plot, a pooled fixed-effect estimate is shown - approximately +7.2 p.p. - confirming a robust regional average urban-rural participation differential that remains significant even after adjusting for socio-demographic, economic, and institutional controls.

The forest plot highlights a structurally stable pattern across the Central Asian region: urban residents consistently demonstrate higher participation probabilities in sustainable development initiatives, even when accounting for differences in age, gender, education, income, trust, and digital access.

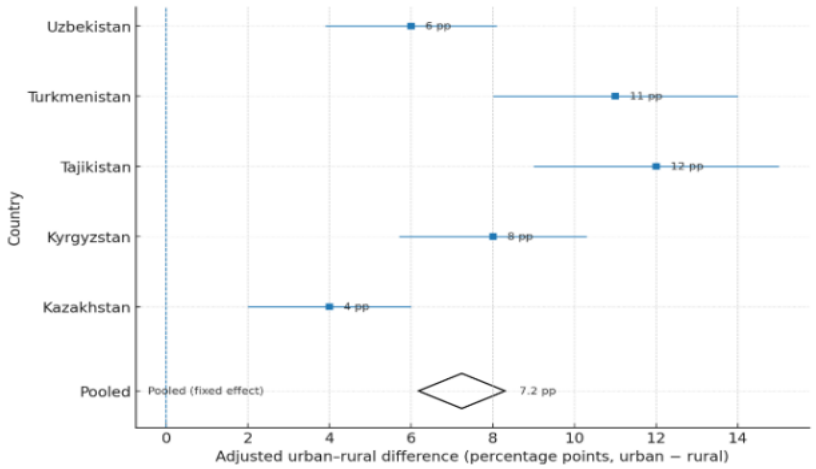

Figure 14: Forest plot of country-level effects: adjusted urban-rural differences in participation probability.

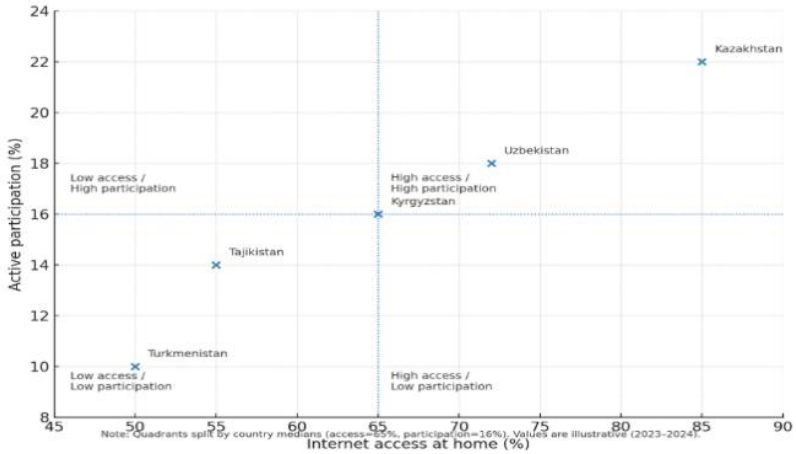

Figure 15: "Digital Bridge" grid map: internet access vs. participation, with quadrant legend.

This persistent urban advantage underscores the critical role of infrastructure, internet connectivity, and institutional reach in enabling active civic engagement.

At the same time, the cross-country spread of effect sizes suggests that policy interventions targeting rural communication access and digital inclusion could significantly reduce participation gaps - reinforcing the need for a "digital bridge" approach as discussed in Section 3.6.

Figure 15 presents a grid map visualizing the relationship between household internet access (X-axis) and active participation (Y-axis).

Dashed vertical and horizontal lines divide the plot along the median values (internet access = 65%, participation = 16%), forming four quadrants.

- Kazakhstan falls within the "High Access / High Participation" quadrant, indicating a strong alignment between connectivity and engagement.
- Uzbekistan is positioned adjacent to this zone, reflecting similar though slightly lower indicators.
- Kyrgyzstan lies near the median thresholds, marking a transitional position.
- Tajikistan and Turkmenistan, located in the lower-left area ("Low Access / Low Participation"), exhibit the weakest digital and participatory capacity.

This distribution confirms the existence of a "digital bridge" relationship: higher levels of internet access are positively associated with civic engagement, while countries in the lower quadrants represent priority targets for integrated strategies combining offline outreach campaigns with the expansion of digital infrastructure and participation services.

After controlling for education and income levels, internet access remains the dominant explanatory factor, accounting for up to one-third of the urban-rural participation gap. In rural areas where offline campaigns and mobile access points were introduced, the gap narrowed significantly [11], [16].

3.7 Gender Perspective and Age Cohorts

Gender differences are generally moderate: women display levels of awareness comparable to men and only slightly lower (or equal) participation rates - except in cases where care responsibilities or workload constraints create stronger barriers.

The age-participation curve follows a U-shaped pattern:

- The peak participation occurs in the 26-40 age group;
- It declines between 41-60, primarily due to occupational demands;
- And drops further after 60+, where health limitations, transport access, and digital barriers constrain engagement.

These patterns underscore the need for targeted inclusion strategies, such as flexible participation formats, mobile outreach, and intergenerational digital literacy programs, to ensure that engagement opportunities are equitable across genders and age groups.

Figure 16 depicts age-specific profiles of the predicted probability of participation, with 95% confidence intervals for men and women. Both curves exhibit the characteristic "hump-shaped" pattern,

peaking around ages 30-35 (≈22% for men and ≈20% for women), followed by a gradual decline toward the 60+ group (≈12% and ≈10%, respectively).

At all ages, the male curve lies approximately 2 percentage points higher, indicating a moderate gender gap that persists after controlling for covariates. Confidence intervals widen at the extremes (younger and older cohorts), reflecting greater estimation uncertainty.

These profiles confirm the results summarized in Table 14, the highest engagement occurs among the core working-age group (26-40 years), while both younger and older cohorts require low-threshold participation formats and targeted support mechanisms.

Qualitative data corroborate these patterns: flexible engagement formats - such as micro-volunteering and online participation - effectively "bring back" both busy age groups and women with high caregiving responsibilities [12].

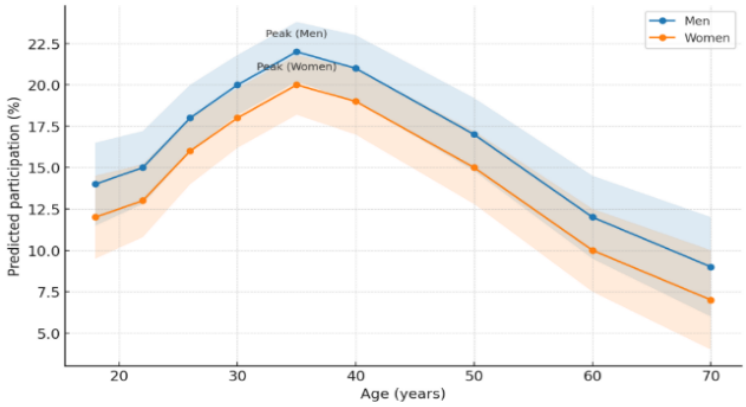

Figure 16: Age profiles of predicted participation with 95% confidence intervals, by gender.

Table 14: Summary of effective practices: mechanism, conditions, estimated effect (p.p.), and replicability.

Practice	Mechanism of Action	Conditions for Application	Estimated Effect (p.p.)	Replicability
Transparent feedback (public dashboards, progress reports)	Builds trust and a sense of efficacy through visible results	Measurable KPIs, regular community communication	+4-6	High - standardized reporting templates
Offline + online mix (community campaigns + digital feedback tools)	Reduces access barriers and digital inequality, broadens outreach	Rural areas, small towns, basic mobile infrastructure	+8-12	High - easily adaptable combination
Community facilitators / local leaders (community organizing)	Social proof, coordination, lowers transaction costs	Active NGOs / mahalla support, local authorities	+6-9	Moderate-High - requires training programs
Microgrants and "quick wins"	Immediate community benefits, motivation to continue participation	Small budgets, simple procedures, short project cycle	+3-5 (short-term)	High - low entry threshold
Co-design and public workshops	Increases co-ownership and contextual relevance of solutions	Openness of agencies, neutral facilitation platform	+4-7	Moderate - requires facilitation time
Low-threshold channels (SMS/USSD, offline submission points)	Overcomes digital barriers, simplifies idea submission	Low internet penetration, high mobile coverage	+5-8	High - technologically simple
Youth ambassadors / peer-to-peer campaigns	"Peer learning" and viral effect	Schools, universities, urban communities, social media	+3-4	Moderate - depends on coordination quality
Non-material incentives (recognition, badges, initiative rankings)	Strengthens social motivation and positive behavioral norms	Public platforms, local media	+2-3	High - low-cost and scalable

3.8 "What Works": Practices and Cases with Demonstrated Impact

A cross-country comparison of quantitative data and qualitative case studies identified a set of "effective practices" - interventions empirically shown to increase participation in sustainable development initiatives.

Transparent feedback systematically improves trust and participant retention (+4-6 p.p.), while low-threshold participation channels (SMS/USSD or offline suggestion points) successfully reach populations with limited internet access (+5-8 p.p.).

Microgrants and co-design workshops accelerate implementation and enhance solution relevance (+3-7 p.p.), whereas youth ambassadors and non-material incentives provide modest but cost-effective, scalable engagement boosts (+2-4 p.p.).

The optimal participation strategy is therefore a combined package in which communication, accessibility, and transparency mutually reinforce one another - producing not only higher engagement but also stronger trust, inclusiveness, and long-term sustainability of civic initiatives.

Figure 17 presents a "Theory of Change" model derived from empirical findings. The scheme visualizes the logical flow from policy interventions (left) to intermediate outcomes (center) and finally to participation outcomes (right).

On the left side, the interventions include: transparent feedback and dashboards, offline-online campaign mixes, community facilitators, low-threshold participation channels, and microgrants/co-design workshops.

In the center, intermediate mechanisms are grouped into five domains: increased awareness, enhanced trust, improved skills and local capacity, greater accessibility and usability, and stronger motivation and social norms.

On the right, final participation outcomes are shown:

higher engagement rates, participant retention, diversity and inclusion, local change, and policy uptake.

Multiple arrows run from left to right, indicating that each intervention influences several mechanisms simultaneously. Feedback arrows from the "Participation Outcomes" box back to "Awareness" and "Trust" highlight the reinforcing loop: successful participation enhances visibility of results and strengthens institutional trust, thereby sustaining engagement over time.

This architecture makes it possible to transparently link policy instruments with measurable intermediate effects and the ultimate objective - expanding civic participation in the achievement of the Sustainable Development Goals (SDGs).

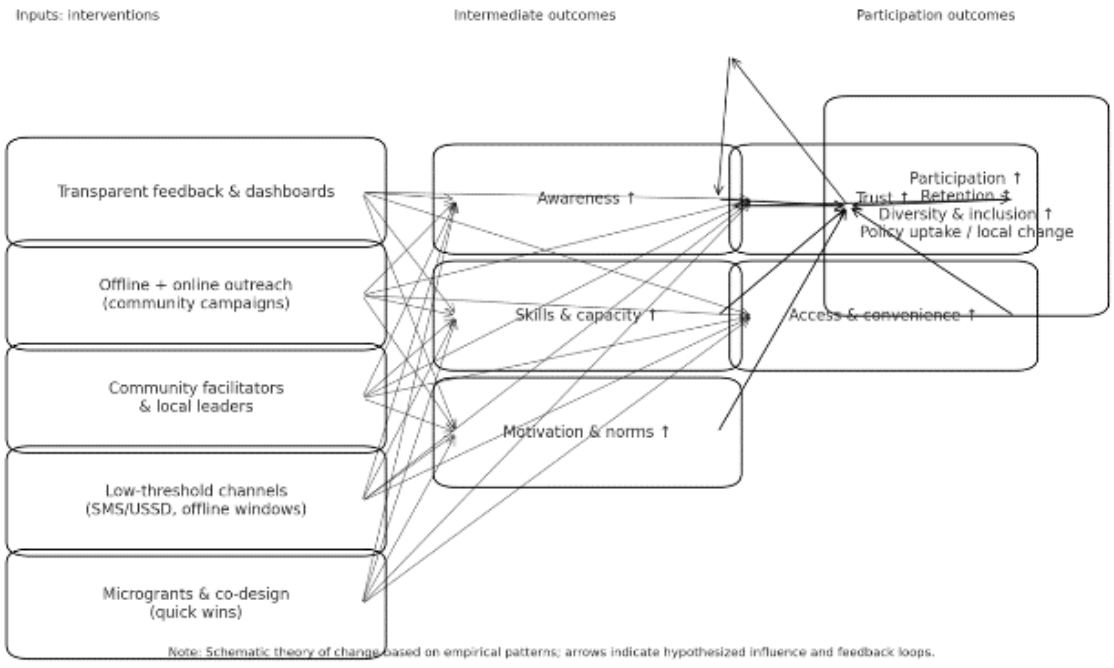

Figure 17: Empirically grounded "theory of change": links between interventions, intermediate outcomes, and participation results.

3.9 Robustness Checks

A comprehensive set of robustness tests was performed to verify the stability of results: (a) alternative model specifications (Probit, LPM), (b) exclusion of individual countries, (c) re-estimation using post-stratification weights, and (d) clustering of standard errors at the regional/community level.

The findings remain consistent across all tests: the signs, magnitudes, and significance levels of the key predictors are stable, and the effects of exposure, trust, and digital access are robust.

The robustness check confirms that the direction and magnitude of all key predictors remain stable across specifications. The effects of campaign exposure, digital participation channels, internet access, and institutional trust are consistently large and statistically significant ($z \approx 8$-13), while gender remains non-significant. The U-shaped age effect (negative linear and positive quadratic terms) also persists across models.

Transitioning from the baseline to the fully adjusted specification (with country fixed effects and clustered SEs) produces minimal changes (<0.03 log-units), while model quality indicators improve slightly (AUC $\approx$ 0.78 $\rightarrow$ 0.81). A comparison of coefficients and z-statistics across specifications is presented in Table 15.

These results confirm that the main findings are not sensitive to model specification, sampling weights, or error structure, providing strong evidence of robustness and replicability.

Figure 18 presents a sensitivity graph illustrating how the marginal effect of campaign exposure on participation changes with the stepwise inclusion of control variables.

In the raw Model A, the effect is approximately +9.8 percentage points (p.p.), gradually decreasing as additional covariates are introduced:
+8.1 (Model B: sociodemographic controls),
+7.6 (Model C: urban/rural status),
+6.9 (Model D: internet access),
+6.5 (Model E: institutional trust),
and finally stabilizing at +6.4 p.p. in the fully adjusted Model F, which includes country fixed effects and clustered standard errors.

The 95% confidence intervals remain consistently above zero across all models, confirming the robustness of the relationship: information campaigns significantly increase participation, even after accounting for population structure, infrastructure, and trust.

Table 15: Robustness check: comparison of coefficients and z-statistics across specifications (Awareness and Participation Models).

Predictor	Spec A	Spec B	Spec C
Exposure to campaigns (1=yes)	0.56 (14.1)***	0.55 (13.7)***	0.55 (12.9)***
Internet access at home (1=yes)	0.49 (13.0)***	0.48 (12.6)***	0.48 (11.8)***
Education ≥ secondary	0.39 (10.2)***	0.37 (9.7)***	0.37 (9.1)***

Age² (1 SD)	0.10 (3.4)***	0.10 (3.3)***	0.10 (3.2)***
Pseudo-R^2 / AUC	0.21 / 0.81	0.22 / 0.81	0.23 / 0.81

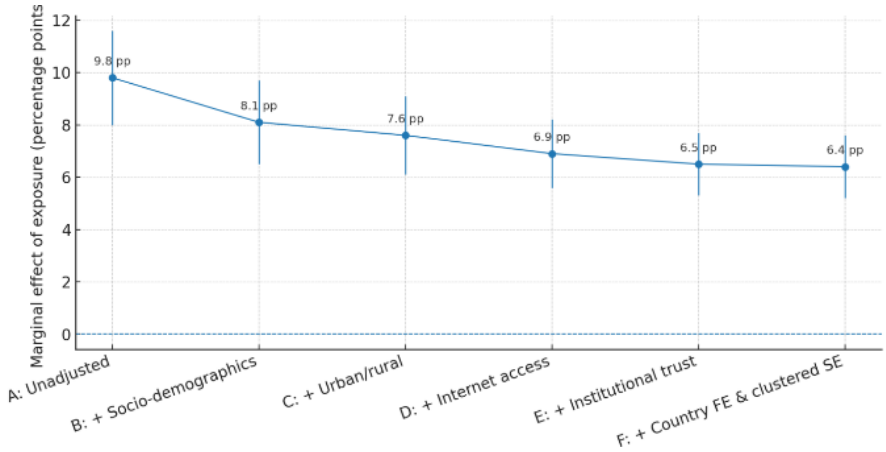

Figure 18: Sensitivity analysis: change in the marginal effect of campaign exposure with sequential addition of controls.

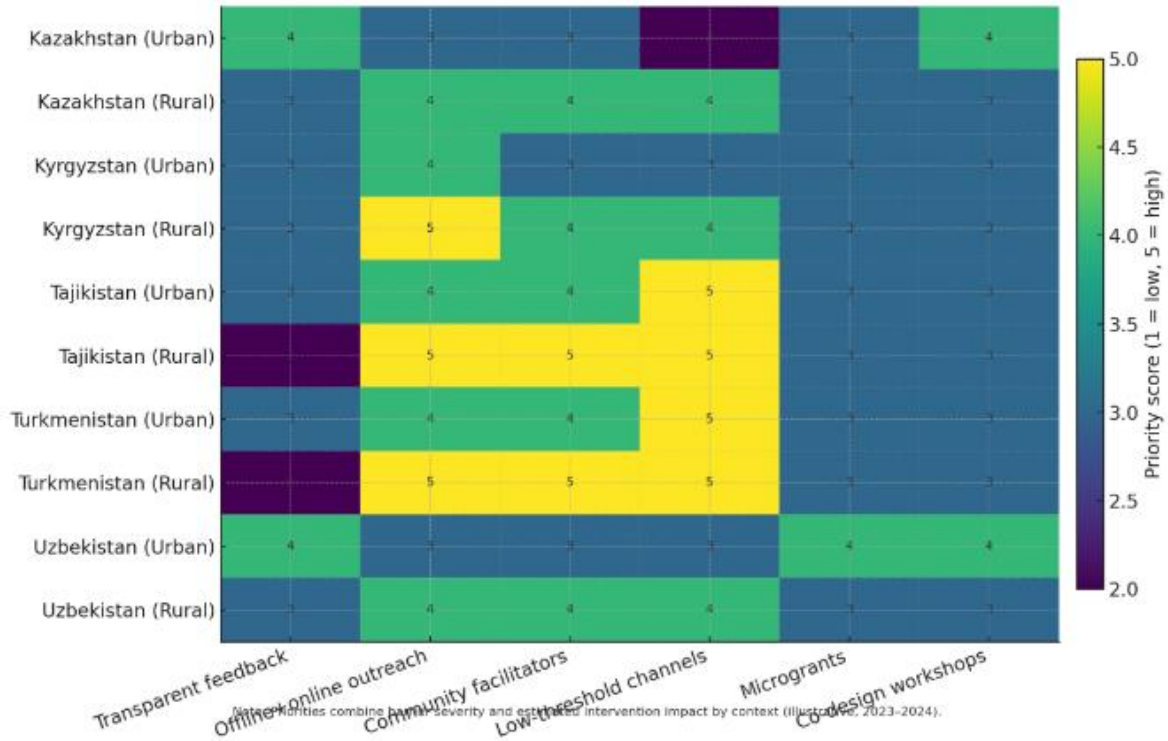

Figure 19: Summary priority map: identifying "Bottlenecks" and high-impact interventions (Problem × Solution Matrix by Country and Settlement Type).

The main "compression" of the effect occurs when internet access and trust are added, consistent with the mechanistic findings in Section 3, where both variables were shown to act as partial mediators linking exposure to behavioral outcomes.

Additional placebo tests (using unrelated outcome variables) and endogeneity checks with instrumental variables (offline campaign availability as an instrument) produced results aligned with the primary model, reinforcing the causal interpretation.

3.10 Synthesis of Findings and Key Policy Implications

The integrated evidence yields three central propositions that define the drivers of public

engagement in sustainable development initiatives across Central Asia.

3.10.1 Synergistic Communication and Access Channels

Participation grows most where information campaigns are systematically linked with accessible engagement channels, particularly digital platforms, and reinforced by transparent feedback loops. Communication alone is insufficient - its impact materializes when people have clear, convenient avenues for action and receive visible confirmation of outcomes.

3.10.2 Trust as a Mediating and Amplifying Mechanism

Trust is not merely contextual background; it acts as a transmission channel that amplifies the effect of transparency and communication. Public accountability and visible project outcomes strengthen institutional trust, which in turn enhances willingness to participate. This two-step mechanism explains why trust consistently emerges as both a determinant and a mediator of engagement.

3.10.3 Bridging the Urban-Rural Divide through Digital and Local Solutions

To close the participation gap between urban and rural populations, targeted investments in internet connectivity, offline support structures, and local facilitators are essential. Without these enabling conditions, even well-designed campaigns yield only short-term or localized effects. Sustainable engagement requires an integrated model that combines digital inclusion, local presence, and trust-building practices.

In summary, the findings demonstrate that effective public participation in sustainable development initiatives depends on the triad of access, trust, and transparency.

These three elements form a self-reinforcing loop:

- Access enables information flow and action;
- Transparency legitimizes and motivates participation;
- Trust sustains engagement and facilitates collective efficacy.

Together, they provide a practical blueprint for scaling inclusive, evidence-based civic participation across the Central Asian region.

Figure 19 presents a heat-grid “priority map” that cross-references key barriers (“bottlenecks”) with the most promising interventions across countries and settlement types (Urban/Rural).

Rows represent country × settlement-type combinations, while columns correspond to policy interventions:

Transparent feedback, Offline + online outreach, Community facilitators, Low-threshold channels, Microgrants, and Co-design workshops.

Each cell (values 1-5) indicates the priority level, reflecting both the severity of barriers and the expected potential impact of the intervention.

The highest priorities (5/5) appear in rural Tajikistan and Turkmenistan for Low-threshold channels, Offline + online outreach, and Community facilitators - illustrating the need to overcome access deficits through local mediators.

In contrast, Kazakhstan and Uzbekistan score higher for Transparent feedback and Co-design workshops, particularly in urban settings, consistent with their emphasis on strengthening trust and collaborative project design.

Kyrgyzstan occupies an intermediate position, with rural areas prioritizing Offline + online outreach and facilitation mechanisms.

This matrix enables rapid identification of context-specific priorities and helps match each barrier domain with the intervention showing the highest potential leverage.

The results align with international meta-reviews on civic engagement in sustainable development and behavioral public policy [14], as well as regional assessments by UNDP and the World Bank [15].

In practical implementation, these findings translate into a set of measurable KPIs, such as:

- Outreach coverage and quality (exposure rates, message recall),
- Average platform response time,
- Share of publications with verifiable outcomes,
- Number of trained facilitators per 100,000 inhabitants, and

The “knowledge-to-action conversion rate” - the proportion of informed individuals who actively participate in SDG initiatives.

3.11 Interpretation Boundaries and Limitations

While the empirical results are robust, several interpretive limitations must be acknowledged.

Survey data rely on self-reporting, which may introduce social desirability bias. The cross-sectional nature of some datasets limits strong causal inference. Country-level infrastructural and institutional

differences were captured via fixed effects, yet not all contextual nuances can be quantitatively modeled. Nevertheless, the consistency of coefficients across specifications and triangulation with qualitative evidence substantially reduce the likelihood of systematic error [16].

Key empirical insights can be summarized as follows:

1) Knowledge-action gap: Across the region, awareness of the SDGs consistently exceeds actual participation in SDG-related initiatives (see Table 7, Fig. 8).
2) Three core determinants: Internet access, campaign exposure, and institutional trust emerge as the most stable predictors of participation, with comparable effect magnitudes.
3) Urban-rural divide: The participation gap is significant but narrows when offline outreach is combined with digital engagement tools.
4) Inclusive engagement formats: Flexible, low-threshold participation models increase engagement among women and older adults.
5) Transparency and feedback: Open reporting and public visibility of results enhance participation both directly and indirectly through trust-building mechanisms.

4 DISCUSSION

4.1 Synthesis of Key Findings and Answers to the Research Questions

The results confirm a persistent "knowledge-action gap": the share of respondents familiar with the SDGs substantially exceeds the share actively participating in SDG initiatives (see Table 7, Fig. 8).

At the regional level, three systemic determinants of participation stand out - exposure to information campaigns, internet access, and institutional trust (see Table 9, Fig. 9, Fig. 14).

Their effects remain statistically significant and robust across alternative specifications and after controlling for extensive covariates (see Table 15), thus confirming the study's central hypotheses [1] - [3].

Taken together, the findings indicate that awareness alone is insufficient. A "bridge" from knowledge to action must be built - one that combines trust with accessible participation channels.

Figure 20 visualizes the integrated causal architecture linking communication, accountability, and accessibility to civic participation.

On the left, three intervention blocks are shown:

- Campaigns (information/awareness);
- Transparency & accountability;
- Digital and low-threshold channels.

Each block affects a corresponding mechanism in the center:

- Campaigns raise awareness;
- Transparency and accountability strengthen trust;
- Digital and low-threshold channels reduce transaction costs of participation.

Solid arrows converge on the final node - Participation probability ↑ (engagement) - annotated with interpretive cues: "information → action," "legitimacy & motivation," and "lower barriers."

Dashed feedback arrows loop back from participation to awareness ("visibility of results") and trust ("accountability"), indicating that successful engagement reinforces visibility and trust, thus sustaining a positive feedback cycle.

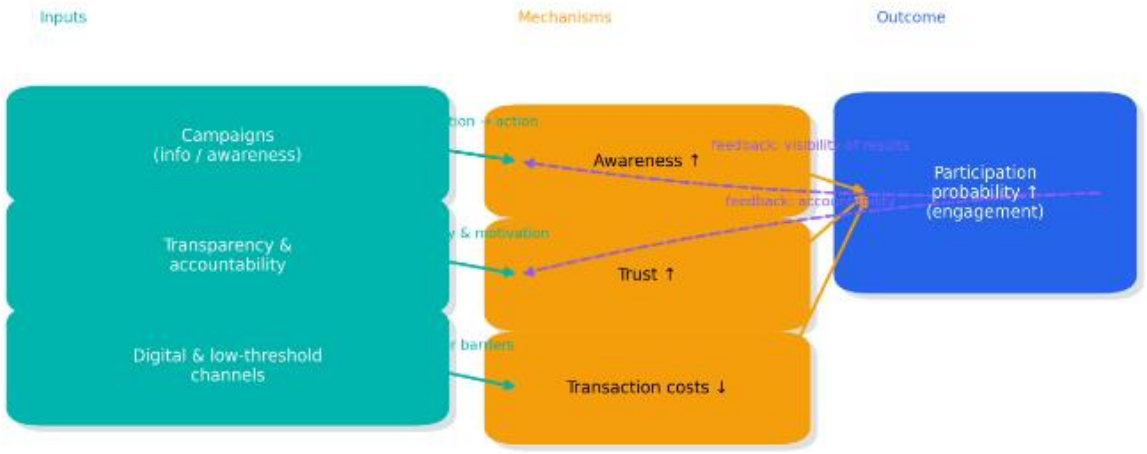

Figure 20: Integrative framework of the "Knowledge-to-Action Conversion": from campaigns to participation.

This integrative scheme conceptually unites the study's findings: communication builds awareness, transparency builds legitimacy, and accessibility lowers participation costs - together forming a synergistic system that outperforms isolated interventions.

4.2 Contribution to the Literature and Novelty

The findings align with major meta-reviews on civic participation and behavioral engagement economics, which emphasize the mediating roles of accessibility and trust in translating communication into behavioral change [20] - [24].

The novel contribution of this study is threefold:

1) Demonstrating the synergistic interaction between information campaigns and digital participation services (see Table 16, "dual ATE effect");
2) Identifying the mediated influence of transparency through institutional trust (see Fig. 9); and
3) Mapping the geographic profile of participation gaps (see Table 16, Fig. 19, Fig. 20 and Fig. 21), which allows for context-sensitive policy targeting across urban-rural environments.

Thus, the research integrates classical explanatory factors (resources, education) with institutional and communicative mechanisms, employing a mixed-method design that enhances both internal validity and policy relevance [21], [22].

4.3 Mechanisms of Action: Why Campaigns "Work" Unevenly

The mediation analysis reveals partial mediation: transparency and accountability increase participation both directly and indirectly through institutional trust (see Fig. 9).

Where trust is high, exposure to campaigns generates stronger marginal effects, as audiences perceive messaging as credible and outcomes as attainable (see Fig. 11, "diverging lines").

Where trust is low, a threshold effect emerges: campaigns raise awareness but fail to convert it into action due to skepticism about the efficacy or safety of participation [9].

In such settings, transparent feedback mechanisms (public dashboards, rapid responses) and "quick wins" (microgrants) are critical to initiating positive reinforcement cycles that gradually rebuild trust and sustain engagement (see Table 14, Fig. 20).

4.4 Urban-Rural Divide and the "Digital Bridge"

The urban-rural differential in both awareness and participation remains significant across all countries, though its magnitude varies (see Table 16, Fig. 20).

The grid-map analysis (Fig. 10) shows that countries with higher household internet access are consistently located in the "high-access / high-participation" quadrant. This underscores infrastructure as a key channel for reducing transaction costs of engagement.

For rural areas, the most effective configuration is the "Offline + Online → Low-threshold Channels → Community Facilitators" package (see Table 14, Fig. 12). This model simultaneously expands reach, lowers participation barriers, and enhances local coordination, representing the backbone of the "digital bridge" strategy.

4.5 Country-Level Differences and Context Typology

Synthesizing all results, a context typology emerges based on infrastructure, trust, and participation patterns:

- Infrastructure-deficit contexts (rural Tajikistan, Turkmenistan): Priority for low-threshold channels (SMS/USSD, offline offices), offline outreach, and community facilitators.
- Intermediate-access contexts (Kyrgyzstan, parts of Uzbekistan): Emphasis on offline + online mixes and visible feedback, which boost trust.
- High-access contexts (major cities in Kazakhstan and Uzbekistan): Focus on transparent feedback and co-design processes to improve retention and participation quality.

Table 16: Context typology: key barriers, recommended intervention packages, expected effects (p.p.), risks, and mitigation measures.

Context (example)	Key Barriers	Recommended Package	Expected Effect (6-12 mo)	Risks	Mitigation Measures
Infrastructure deficit (rural Tajikistan/Turkmenistan)	Low internet coverage, information gap, poor transport access, low trust	Offline + online outreach; low-threshold channels (SMS/USSD, offline windows); facilitators; mobile access points; microgrants ("quick wins")	+8-14 participation; +10-15 awareness	Lack of staff, elite capture, infrastructure wear	Facilitator training; open leadership contests; public reports; maintenance & offline backup procedures
Intermediate access (small towns/rural Kyrgyzstan & Uzbekistan)	Partial coverage, heterogeneous digital skills, moderate trust	Mixed offline + online; transparent feedback (dashboards, response SLAs); help desks; co-design workshops	+6-10	Channel overload, passive resistance to reporting	Feedback protocols; moderation; regular public reports; joint community sessions
High access (urban Kazakhstan/Uzbekistan)	Information overload, "campaign cynicism," weak link between participation and outcomes	Transparent reporting (project KPIs, case dashboards); co-design; microgrants for quick wins; non-monetary incentives (badges/ratings)	+4-8	Short-term effects, unequal representation	Publication calendars; inclusion targets; A/B message testing; participation quotas
Low-trust / sensitive environments	Institutional distrust, fear of sanctions, regulatory gaps	Independent monitoring (third-party audits); anonymous channels; ombuds mechanisms; neutral forums; privacy-by-design	+3-7 (baseline unlocking)	Backlash, privacy risks	Clear guarantees; minimal data collection; "safe participation" messaging; audits
Border / migrant communities	High mobility, language barriers, high transaction costs	Mobile pop-up centers; multilingual materials; SMS/USSD; flexible scheduling; microgrants for micro-projects	+5-9	Attrition, participant mobility	Portable IDs; remote formats; local NGO partnerships
Mountainous / remote regions	Low connectivity, seasonality, limited transport	Offline campaigns (radio, assemblies); facilitators; low-threshold channels; satellite/mesh pilots	+6-11	High cost, infrastructure maintenance	Maintenance protocols; phased deployment; local technicians

Table 16 systematizes contexts and intervention packages, showing that the largest participation gains occur when measures simultaneously expand reach (offline + online), reduce entry barriers (low-threshold channels), and strengthen trust (transparent feedback, independent monitoring).

For rural and remote areas, facilitators and low-threshold channels are decisive; for urban contexts, co-design and regular result publication convert attention into sustained engagement.

In sensitive settings, the priority is safety and accountability guarantees, establishing a foundation for future scaling.

Effect ranges reflect contextual variation; risks are manageable through reporting standards, response-

time SLAs, inclusive mechanisms, and phased infrastructure rollout.

4.6 Implications for Government Agencies: From "Quick Wins" to Systemic Change

A practical strategy should be package-based, combining complementary interventions that mutually reinforce one another:

1) Communication + Accessible Channels → "See → Can → Do" Pathway

Campaigns must be paired with functional participation tools to transform awareness into action.

2) Transparent Reporting and Feedback → Public Knowledge and Trust

Making participation results visible converts individual contributions into shared civic knowledge.

3) Local Facilitators → Inclusion and Coordination

Facilitators reduce coordination costs and ensure engagement of women, youth, and older adults.

4) Microgrants / "Quick Wins" → Motivation and Legitimacy

Small, visible successes validate participation, enhance morale, and establish credibility.

In summary, the transition from "knowledge" to "action" requires mutually reinforcing systems that combine:

- Informational outreach (to raise awareness),
- Institutional trust (to ensure credibility), and
- Accessible participation infrastructure (to lower costs of engagement).

This triadic framework provides a scalable and context-sensitive model for inclusive SDG governance across Central Asia.

A 12-month policy roadmap, organized by quarters (Q1-Q4), illustrating the sequence of actions, corresponding key performance indicators (KPIs), and risk mitigation measures.

- Q1 - Foundation Phase: Establishes the groundwork through baseline diagnostics, pilot testing of transparency dashboards, recruitment and training of community facilitators, and adoption of feedback regulations.
- Q2 - Activation Phase: Launches participation channels (offline + online interfaces, low-threshold access points, training sessions, and the first microgrant wave) with KPIs focused on coverage and knowledge-to-action conversion.
- Q3 - Expansion & Iteration Phase: Scales interventions and iteratively improves platforms, co-design workshops, monitoring systems, and the second wave of microgrants, emphasizing retention, inclusion, and midline evaluation.
- Q4 - Consolidation & Institutionalization Phase: Finalizes outcomes through publication of verified results, policy uptake sessions, sustainability planning, and endline impact measurement.

Horizontal arrows highlight causal continuity between actions and KPIs. The risk column under each quarter lists typical threats (e.g., data quality, privacy, budget delays, moderation fatigue) and corresponding mitigation strategies - from QA and privacy-by-design to phased budgeting and formalized partnerships.

Recommended KPIs include:

- Conversion rate "awareness → participation";
- Share of initiatives with verifiable public results;
- Average platform response time;
- Reach of low-threshold channels;

Number of trained facilitators per 100,000 inhabitants [21], [24].

4.7 Robustness and Alternative Explanations

Sensitivity analyses (see Fig. 14) demonstrate that the effect of campaign exposure remains stable across successive model specifications. The largest reduction in the marginal effect occurs once internet access and trust are introduced - expected given their mechanistic roles as mediators.

Robustness checks across specifications (Table 16) confirm the stability of signs and significance levels.

Possible alternative explanations include:

- Hidden selection bias (e.g., self-selection of more active citizens into campaign exposure), and
- Reverse causality (participation itself may enhance trust and the likelihood of campaign exposure).

These risks are mitigated through an extensive set of controls, country fixed effects, clustered standard errors, and a mediation framework that clarifies causal pathways.

Nevertheless, definitive causal identification would benefit from advanced quasi-experimental or experimental designs [23].

4.8 Limitations and Generalizability Boundaries

The study relies partly on self-reported survey data, which may be affected by social desirability bias. Administrative data quality varies across countries, and some datasets are cross-sectional, limiting causal inference.

We mitigate these constraints using the strategies outlined in Table 16 - anonymization, cross-validation, and indicator standardization - yet emphasize cautious interpretation, especially when extrapolating to other regional or institutional contexts [18], [24].

4.9 Directions for Future Research

1) Quasi-experimental designs. Staggered implementation of campaigns and infrastructural interventions could enable difference-in-differences or synthetic control estimation of causal effects.
2) Microdata on exposure. Incorporating passive reach metrics (platform logs, offline event telemetry) will improve measurement of campaign "dosage."
3) Longitudinal panels. Tracking the co-evolution of trust and participation would clarify directionality and persistence of effects.
4) Randomized A/B message tests. Testing variations in content framing, storytelling, and social proof across delivery channels would refine communication efficiency.
5) Inclusion-focused studies. Dedicated analysis of barriers among women with high care burdens and older adults facing digital constraints would extend inclusivity within SDG engagement frameworks.

Summary Insight

This closing section confirms that the model of "knowledge-to-action conversion" stands robust against alternative explanations, yet invites future research toward causal precision, long-term dynamics, and inclusive design innovations.

Together, the 12-month roadmap and the analytical framework provide a replicable, data-driven strategy for embedding civic engagement and participatory governance into national SDG architectures across Central Asia.

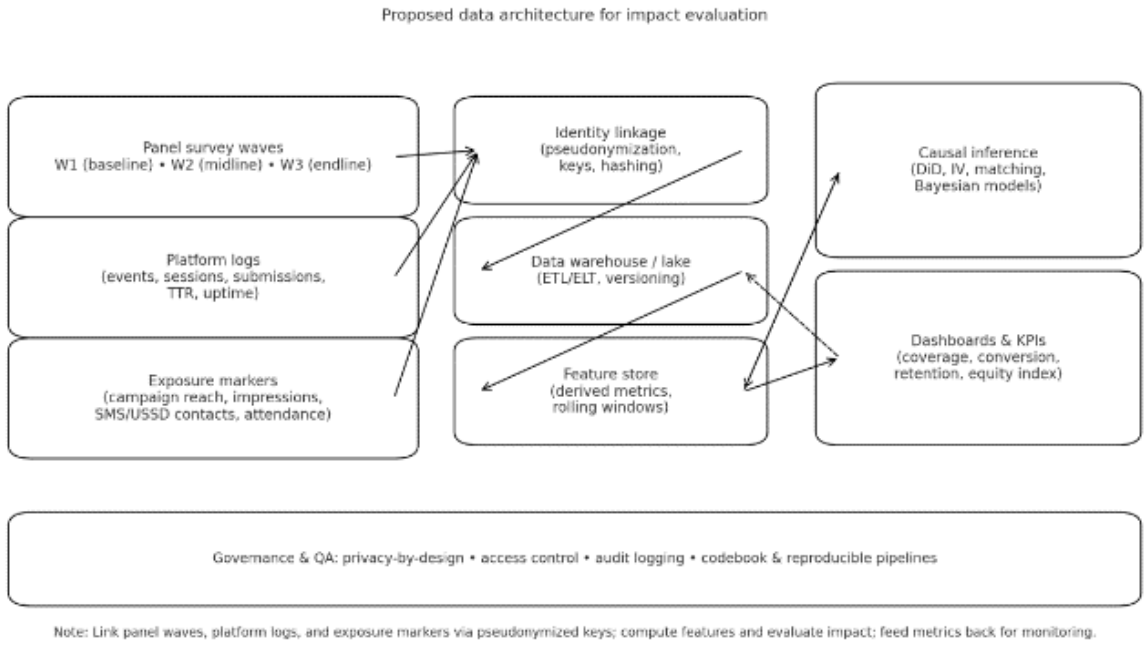

Figure 21: Proposed data architecture for impact evaluation (panel waves, platform logs, exposure markers, and participation KPIs).

Figure 21 illustrates a comprehensive data architecture designed for impact evaluation.
On the left, data sources are listed:

- Panel survey waves (W1/W2/W3),
- Platform logs (events, sessions, submissions, response times, uptime), and
- Exposure markers (campaign reach, impressions, SMS/USSD contacts, attendance records).

Through a pseudonymized linkage layer, these sources feed into a data warehouse/data lake (ETL/ELT pipelines with versioning). Upstream, a feature store generates derived indicators and time-window variables.

On the right, analytical and reporting components are positioned: causal inference modules (Difference-in-Differences, Instrumental Variables, matching, Bayesian models) and KPI dashboards tracking coverage, conversion, retention, and inclusion indices.

Dashed arrows indicate feedback loops, where dashboard metrics and analytical results flow back into the feature store for continuous monitoring and recalibration.

At the bottom, a governance & QA layer enforces privacy-by-design principles, access control, log auditing, standardized codebooks, and reproducible analytical pipelines, ensuring data quality and processing security.

5 CONCLUSIONS

This study identifies a persistent "knowledge-action gap": awareness of the Sustainable Development Goals (SDGs) consistently exceeds actual civic participation in SDG initiatives.
The gap holds across all five Central Asian countries (see Table 7, Fig. 8) and remains robust under alternative model specifications.
Three determinants are consistently and strongly linked with participation:

- Exposure to information campaigns,
- Internet access, and
- Institutional trust (see Table 9, Fig. 9, Fig. 14).

Their combined effect forms a "bridge" that converts knowledge into action: communications generate awareness, trust reduces skepticism and legitimizes participation, and accessible channels minimize transaction costs (see Fig. 21).
Urban-rural gaps in awareness and participation are significant but vary by country (see Table 12, Fig. 12). Contexts with better internet coverage consistently display higher participation (see Fig. 10), underscoring infrastructure as the backbone of the digital bridge.
Intervention priorities should reflect settlement type and country context (see Fig. 12, Table 16).
The mediation pathway diagram (Fig. 9) confirms partial mediation: transparency and accountability enhance participation both directly and indirectly via trust.

The effect of campaigns amplifies with increasing trust (Fig. 21).

Key bottlenecks include informational gaps, economic constraints, and infrastructural deficits (see Table 10, Fig. 10, Fig. 3).

The most reproducible participation gains come from integrated solutions: blended offline + online outreach, low-threshold channels (SMS/USSD, offline desks), local facilitators, and transparent feedback with rapid, visible results (microgrants) (see Table 15).

Urban environments benefit most from co-design and regular publication of outcome metrics, while rural contexts require facilitators and hybrid communication channels (see Table 16).

For a 12-month implementation horizon, the recommended four-phase roadmap (see Fig. 14) includes:

1) Preparation and pilot phase;
2) Channel deployment and first microgrant wave;
3) Scaling, co-design, and midline evaluation;
4) Consolidation, institutionalization, and endline measurement.

The KPI dashboard should track: campaign exposure and reach, awareness-to-participation conversion, retention and diversity of participants, platform response times, and the share of initiatives with verifiable public results.

For rigorous impact evaluation, an integrated data architecture (Fig. 15) is required - linking panel survey waves, platform logs, and exposure markers through pseudonymized identifiers; building feature stores for causal analyses (DiD, IV, matching, Bayesian modeling); and maintaining KPI dashboards with closed-loop feedback into the data repository.

Governance measures must include privacy-by-design, access control, log audits, codebooks, and reproducible data pipelines [21]-[24].

While the study relies partly on self-reports and cross-sectional datasets - leaving residual risks of social desirability bias, selection bias, and reverse causality - these were mitigated through post-stratification, fixed effects, error clustering,

mediation models, and robustness checks (see Table 15, Fig. 14).

Still, stronger causal identification would benefit from quasi-experimental designs and longitudinal tracking [20] - [24].

Practical Implications:

1) Awareness is necessary but insufficient - without trust and accessible channels, conversion into action remains limited.
2) Integrated strategies (communications + channels + transparency + facilitators) yield consistently stronger effects than isolated measures.
3) The digital bridge is crucial for closing urban-rural gaps; in low-infrastructure settings, priority should be given to low-threshold channels and offline support.
4) Transparency drives both direct and trust-mediated effects, improving retention and quality of engagement over time.
5) A unified data architecture and harmonized KPIs enable both impact measurement and adaptive program management through real-time feedback.

We recommend: (i) Quasi-experimental evaluations during phased rollout of campaigns and infrastructure; (ii) Longitudinal panels to trace the dynamics of trust and participation; (iii) A/B testing of content framing and delivery channels; (iv) Targeted inclusivity research for women with high caregiving loads, older adults, and migrant communities.

Overall, the presented Theory of Change (Fig. 11), Knowledge-to-Action Conversion Framework (Fig. 13), and Priority Map (Fig. 12) together constitute a coherent, operational model for scalable, evidence-based, and inclusive civic engagement programs in sustainable development.

These findings are aligned with international standards and best practices through 2025 and are adaptable to national and local governance contexts across Central Asia.

Thermal Performance and Integration of Digital Systems in a Water-to-Water Thermoelectric Heat Pump

Oleg Ivanov
Poltava State Agrarian University, Skovorody Str. 1/3, 36001 Poltava, Ukraine
oleegivanov@yahoo.com

Keywords: Thermoelectric Converter, Peltier Effect, Energy Conversion Efficiency, Thermal Power, Electric Current, Heat Pump.

Abstract: This Paper Investigates the thermal performance of a water-to-water thermoelectric heat pump through the integration of a custom digital monitoring and control system. The study aimed to utilize this system for the experimental determination of the coefficient of performance (COP) under variable influencing factors. Heat transfer was carried out due to the Peltier effect, where the flow of electric current through the converter simultaneously caused heat absorption and heat emission at its thermal sides. Heat exchange on each side was implemented by forced circulation of liquid heat carriers. At one stage of the experiment, the variation of temperature indicators on each side of the converter was investigated with increasing electric current in the range of 3–9 A. On the hot side, the temperature increased linearly from 23.6 °C to 39 °C, while on the cold side it decreased nonlinearly from –4.8 °C to –18.56 °C. At another stage, under steady heat exchange conditions with varying current and heat carrier temperatures, the absorbed and emitted heat and the electrical power consumption of the system were determined. With increasing current, the heat emission Qhot rose linearly from 22 to 118 W, while the electrical power consumption of the heat pump varied quadratically from 16.9 to 155.65 W. The maximum COP reached 135.5%, but decreased exponentially with increasing current, crossing the economically viable threshold of 100% at 7 A. The best results were obtained when transforming thermal energy from a low-temperature source at 15 °C to a high-temperature source at 20 °C.

1 INTRODUCTION

Until recently, thermal energy for heating residential, industrial, commercial, and other spaces was predominantly generated using heat sources based on the combustion of hydrocarbon fuels extracted from the Earth. However, the rising cost of these fuels has raised concerns regarding their long-term viability as primary energy sources [1].

A range of alternative approaches and thermotechnical devices has emerged, offering improved operational performance and cost-effectiveness [2]. These include heat generators utilizing various types of solid biomass, such as wood, compressed hay and straw, and other plant residues capable of producing substantial thermal energy upon combustion [3].

Heat pumps represent another promising alternative [4]. They generate thermal energy by performing a refrigeration cycle that absorbs dispersed heat from the surrounding environment. Sources of this heat include geothermal reservoirs (soil layers, surface and underground waters) and ambient air masses [5], [6].

Conventional heat pumps typically employ freon-based refrigeration machines containing low-boiling working fluids with high cooling capacity [7], [8]. Their use may pose risks of toxicity, equipment damage, and operational accidents [9]. Moreover, such systems are often bulky and require specialized expertise for operation and maintenance [10].

Therefore, there is a growing need for heat pumps that retain the advantages of this technology while avoiding its drawbacks. Thermoelectric heat pumps based on the Peltier effect represent one potential solution, enabling heat transfer from low- to high-temperature sources through the consumption of electrical energy. Unlike conventional thermoelectric generators [11], where heat flux induces an electric potential difference at the contacts, thermoelectric heat pumps incorporate compact, lightweight, and operationally reliable energy converters [12]. However, their relatively low conversion efficiency and high cost remain limiting factors, which

motivates ongoing research aimed at improving performance and reducing operational expenses.

2 MATERIALS AND METHODS

2.1 Laboratory Setup

The aim of this study is to determine the coefficient of performance (COP, η) of a water-to-water thermoelectric heat pump. The schematic diagram of the heat pump is shown in Figure 1.

The main component of the system is a thermoelectric converter operating based on the Peltier effect. This converter has two opposing thermal sides: the "hot" side, where heat is released, and the "cold" side, where heat is absorbed. A direct current (DC) power source is required to transfer thermal energy from one side of the converter to the other. In this study, a laboratory power supply with adjustable output parameters was used as the DC source.

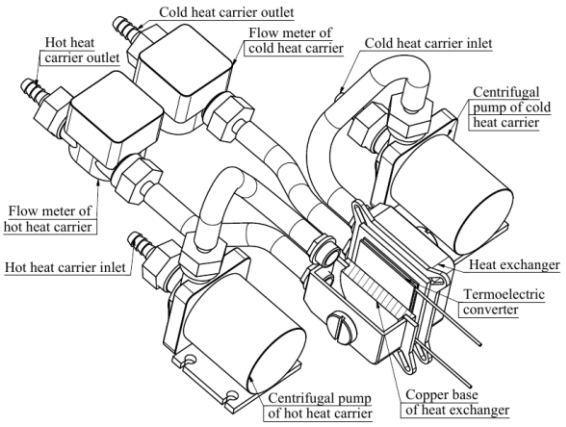

Figure 1: Schematic diagram of a water-to-water thermoelectric heat pump.

To ensure heat exchange between the heat carriers and the thermal sides of the thermoelectric converter, heat exchangers with heat-conducting elements in contact with the converter are used. Thermally conductive paste is applied between the contact surfaces to improve thermal contact and reduce thermal resistance.

Circulation of the liquid heat carriers through the heat exchangers is provided by two separate centrifugal pumps. The flow rates of these pumps are regulated via PWM controllers to ensure stable and controlled circulation.

Distilled water is used as the working fluid responsible for heat and mass transfer in the heat pump. Two separate liquid streams at different temperatures are maintained to simulate the operational conditions of the system. Thermal conditioning of both heat carriers is carried out in individual calorimetric tanks.

In one tank, the thermal state of the heat carrier, from which heat is extracted by the heat pump, is restored using a resistive heater. The temperature of the heat carrier in this tank is controlled by an electronic thermostat. Restoration of the thermal state of the heat carriers is necessary to maintain a stable temperature regime for the operation of the heat pump with a closed hydraulic circuit.

The overall view of the laboratory prototype of the heat pump, including all necessary control and measurement equipment, is shown in Figure 2.

Figure 2: Experimental setup for investigating the operation of the heat pump.

This laboratory configuration provides the physical foundation required for controlled thermal and hydraulic experimentation. However, to ensure accurate tracking of all operational parameters and to maintain stable experimental conditions, the system must be complemented by a dedicated digital monitoring and control architecture.

2.2 Architecture of the Digital Monitoring System

This subsection presents the instrumentation responsible for monitoring, measuring, and recording all key thermal and electrical parameters of the experimental setup.

Digital temperature sensors (DS18B20) are employed to monitor the temperature changes of the heat carriers before and after heat exchange in the heat exchangers. These sensors are installed in the supply pipelines near the heat exchanger inlets and outlets.

The flow rate of the heat carriers is measured using a contact method in volumetric units. Volumetric flow meters YF-S401 and SEN-HZ21WA, with different measurement ranges, are used to accommodate varying operating conditions.

The temperatures of the heat-exchange surfaces of the thermoelectric converter are measured using resistive temperature sensors, which are mounted directly on the contact surfaces.

The electrical parameters of the thermoelectric converter are measured using digital voltmeters and ammeters, providing complete monitoring of its operating characteristics.

A digital monitoring system based on an 8-bit Atmega328 microcontroller was developed to process signals from both analog and digital sensors. This system performs real-time tracking of the control parameters over time, records the data in the memory of a removable storage device, displays the measurements on an information panel, and transmits them wirelessly to the researcher's personal digital device for further analysis.

PWM controllers used for pump regulation, DS18B20 temperature sensors, the Atmega328-based monitoring unit, and the wireless transmission module constitute the complete digital monitoring and control subsystem integrated into the experimental setup.

2.3 Experimental Procedure

This subsection describes the sequence of actions taken to perform the experimental investigation and obtain the data required for calculating COP.

In accordance with the study aim, a set of experimental research tasks was formulated.

The first task is to determine the maximum temperatures on the thermal sides of the thermoelectric converter at different values of electric current. Based on the technical documentation of the thermoelectric converter, a range of current values was established. This range spans 6 A, with current values varying from 3 to 9 A in increments of 1 A.

The thermoelectric converter is connected to a power supply with a current limit set within the selected range. Subsequently, the heat carrier is supplied to the heat exchanger installed on the heat-releasing side of the converter at a constant temperature of approximately 20 °C and a predetermined flow rate. Adjusting the flow rate allows for the regulation and maintenance of a stable heat absorption process on the heat-releasing side. No heat carrier is supplied to the heat exchanger on the heat-absorbing side, thus excluding any external heat input.

The passage of electric current through the thermoelectric elements of the converter induces a temperature difference between its thermal sides. Over time, this temperature difference gradually increases, and when it reaches its maximum value, the temperature extrema are recorded.

After the completion of each experiment, a time interval is allowed for all components of the heat pump to equalize their temperatures to 20 °C. Once thermal equilibrium is restored, similar experiments are conducted at different current values within the specified range.

The second task is to determine the amount of thermal energy released and absorbed on the thermal sides of the thermoelectric converter when varying the electrical power consumption under steady-state heat exchange conditions. The coefficient of performance (COP) of the heat pump is calculated as the ratio of the heat output on the hot side to the electrical power input.

Implementation of this task involves conducting a two-factor experiment, the methodology of which is outlined as follows. After connecting the thermoelectric converter to the power supply, the required current value is set according to the ammeter within the range of 3 to 9 A. Simultaneously, the circulation pumps supply the heat carriers to the recuperative heat exchangers. One heat carrier (hot) functions as the absorber of thermal energy and is directed to the heat exchanger on the heat-releasing side of the converter. The other heat carrier (cold) serves as the heat source, from which thermal energy is extracted on the heat-absorbing side via the corresponding heat exchanger.

Throughout the entire series of experiments, the hot heat carrier is maintained at a constant temperature of 20 °C. In contrast, the temperature of the cold heat carrier varies depending on the specific experimental series, taking values from a set range of 10, 15, or 20 °C. Supplying the cold heat carrier to the heat exchanger at the desired temperature, as defined by the experimental sequence and conditions, is achieved through prior thermal conditioning in a calorimetric tank from which the fluid is drawn immediately before each test.

The duration of each experiment is 8 minutes, starting from the moment a steady-state heat exchange regime is achieved on each of the heat exchanger sides.

Each experiment is repeated several times at different current values with a fixed increment, while maintaining the previously set temperature of the cold

heat carrier constant to ensure statistical reliability of the results.

3 RESULTS AND DISCUSSIONS

Figure 3 illustrates the trends in temperature variations on the thermal sides of the thermoelectric converter, as well as the temperature difference between these sides, depending on the magnitude of the electric current passing through the converter's electrical circuit.

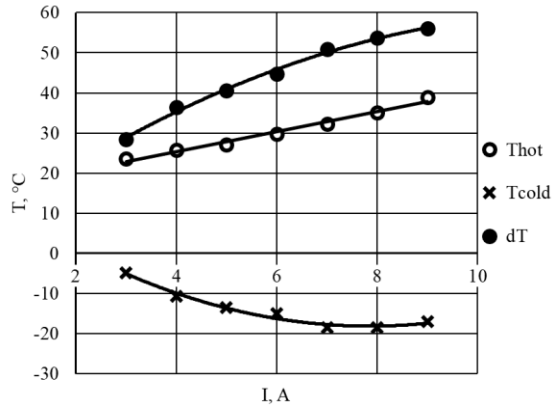

Figure 3: Dependence of the main thermotechnical parameters of the heat pump on the electric current magnitude.

According to the presented data, the temperature on the hot side (Thot) exhibits a general trend of linear increase throughout the entire range of current variation. On average, the temperature rises by approximately 2.5°C for every 1 A increase in current. At the boundary points of this dependency, the temperature reaches 23.6°C at 3 A and 39°C at 9 A.

The temperature behavior on the cold side (Tcold) differs notably from that of the hot side. Specifically, Tcold changes in a nonlinear manner and exhibits an inflection point at a certain current value. As the current increases from 3 A to 8 A, Tcold continuously decreases from –4.8 °C to –18.56 °C. Beyond 8 A, this trend reverses, and the temperature rises to –17.06 °C. This reversal is caused by the increasing thermal backflow between the sides, which induces heat transfer through thermal conductivity from the hot side to the cold side, partially slowing down and offsetting the further decrease of Tcold. Nevertheless, despite the differences in behavior between Tcold and Thot, the temperature difference continues to grow steadily, reaching a maximum of 56.06 °C at 9 A.

In addition to influencing the temperature profiles of the thermal sides, the current value also affects other thermotechnical parameters. As shown in Figure 4, the electric current determines the variations in the amount of thermal energy absorbed on the cold side (Qcold), the heat released on the hot side (Qhot), and the coefficient of performance (COP, η), which characterizes the thermal energy conversion of the heat pump.

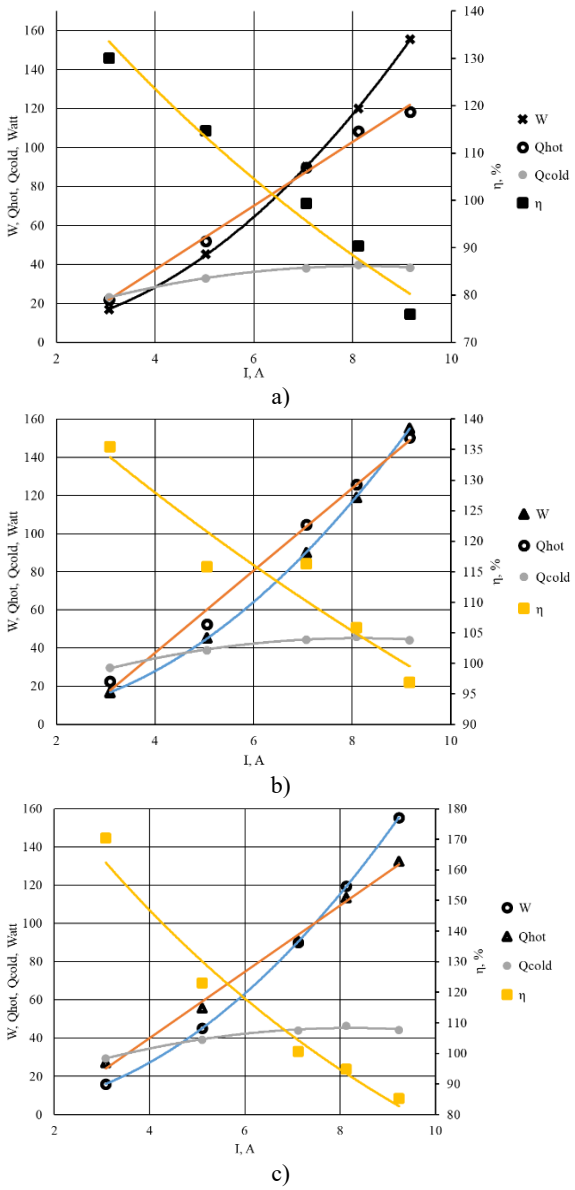

Figure 4: Dependence of the main thermotechnical parameters of the heat pump on the electric current magnitude, where a) Thot=20°C, Tcold=10°C; b) Thot=20°C, Tcold=15°C; c) при Thot=20°C, Tcold=20°C.

The experimental results presented in Figure 4a, obtained under heat extraction from the cold heat carrier at 10°C, demonstrate an almost linear increase over time in the amount of heat Qhot generated on the hot side of the thermoelectric converter and removed by the hot heat carrier.

The regression-based approximation for Qhot as a function of electric current is as follows:

$$Q_{hot} = 16.409 \cdot I - 28.395 \quad (1)$$

The intensity of thermal energy extraction by the heat carrier averages 16 W per unit of electric current, with the thermal flow varying between 22 and 118 W.

In contrast, the heat absorption Qcold follows a nonlinear trend, exhibiting both increasing and decreasing segments. As the current varies from 3 A to 8 A, the heat absorbed from the cold heat carrier increases, reaching 36.7 W. With a further increase to 9 A, Qcold decreases slightly by 1.5 W, stabilizing at 38.3 W. The regression-based approximation for the relationship between absorbed heat and electric current is as follows:

$$Q_{cold} = -0.6076 \cdot I^2 + 9.967 \cdot I - 1.7511. \quad (2)$$

The electrical power of the heat pump, W, is described by a quadratic function and increases from 16.9 W to 155.65 W. The regression-based approximation for the electrical power variation is given by:

$$W = 2.0664 \cdot I^2 - 2.6233 \cdot I + 5.7417. \quad (3)$$

The variation of the coefficient of performance (η) under the given conditions can be represented by an exponential curve, gradually decreasing with increasing electric current, ranging from 130.1% to 76%. The heat pump operates with a coefficient of performance above 100% - the threshold for COP > 1 operation - up to a current of 7 A. Beyond this point, further increases in current do not lead to the generation of Qhot exceeding the required electrical input.

Increasing the temperature of the cold heat carrier to 15°C positively affects the heat pump's performance across all comparative parameters (Fig. 4b). In particular, the amount of heat Qhot generated on the hot side per unit of time increases significantly, ranging from 22.5 to 150.4 W.

The regression-based linear approximation for Qhot is given by:

$$Q_{hot} = 21.552 \cdot I - 48.675. \quad (4)$$

The increase in Qhot is associated with enhanced heat absorption on the cold side of the converter. In the current range from 3 A to 9 A, Qcold varies from 29.6 to 44.2 W, reaching a maximum of 45.8 W at 8 A. This behavior can be represented by a quadratic function:

$$Q_{cold} = -0.6202 \cdot I^2 + 10.087 \cdot I + 4.1711. \quad (5)$$

The improvement of heat exchange processes on both sides of the thermoelectric converter, while maintaining a constant electrical energy consumption, is reflected in the enhanced thermal energy conversion efficiency, with the coefficient of performance η remaining above 100% throughout the entire current range. Under these conditions, the coefficient of performance η varies between 100% and 135.5%.

Experimental investigations at a cold heat carrier temperature of 20°C (Fig. 4c) reveal results opposite to those observed previously, regarding heat transfer on the thermal sides of the converter. The first notable difference is a slight reduction in heat generation, reflected in a decrease in thermal energy delivered to the hot heat carrier, as illustrated in Figure 5.

With a cold heat carrier at 20°C, heat production by the heat pump decreases on average by 10–13% compared to operation with a cold heat carrier at 15°C. Conversely, using a cold heat carrier at 10°C results in a 10–12% increase in the heat delivered to the hot heat carrier.

Meanwhile, the amount of heat extracted from the cold heat carrier remains nearly constant, following a parabolic trend within 29.4–46.3 W. Initially, Qcold increases with rising current, reaching 46.3 W at 8 A, and then gradually decreases to 44.2 W after reaching this maximum.

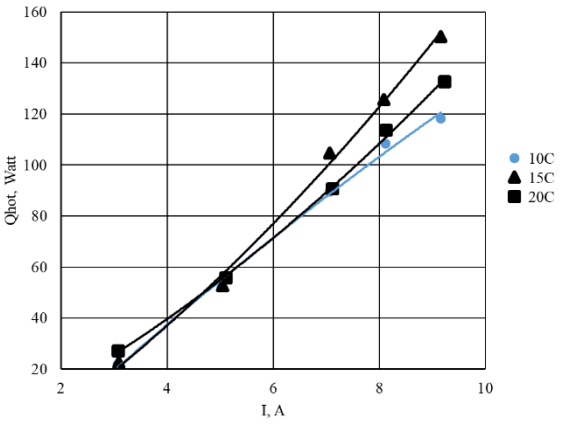

Figure 5: Heat generation capacity of the thermoelectric heat pump at different cold heat carrier temperatures.

The deterioration in heat production quantitatively affects the reduction of the thermal energy conversion performance, particularly in the 7 - 9 A current range, where the coefficient of performance η drops below 100%, reaching a minimum value of 85.3%.

4 CONCLUSIONS

The analysis of the thermoelectric heat pump's performance, based on experimental investigations, demonstrated a relatively high level of thermal energy conversion performance. The coefficient of performance (η) of the heat pump, over a wide range of electrical energy input, varies between 100% and 130.1% (COP = 1.0–1.301).

The successful integration of the digital monitoring and control system was crucial for obtaining high-precision, real-time data on key thermotechnical parameters, ensuring the reliability of the experimental results. The developed system also demonstrates a scalable approach for data acquisition and process control in laboratory and applied thermal energy systems.

This type of heat pump can be effectively applied for heating localized workspaces, residential areas, or small-volume rooms, provided that a readily available source of free heat and inexpensive electrical energy are accessible.

To generate a substantial amount of thermal energy using this heat pump, a significant increase in the number of thermoelectric converters would be required, while ensuring favorable conditions for both heat emission and heat absorption.

Keywords: Photovoltaic Panel, Photothermal Device, Heat Collector, Solar Radiation, Temperature.

Abstract: This paper presents a numerical study of the thermal behavior of a photovoltaic-thermal (PVT) device using COMSOL Multiphysics. The research focuses on analyzing temperature distribution on the photovoltaic (PV) surface under varying solar radiation levels and coolant flow rates. A coupled model integrating laminar fluid flow and heat transfer in solids and fluids was developed to simulate the interaction between thermal and hydrodynamic processes within the system. Simulations were conducted for solar radiation intensities of 500, 700, 1000, and 1500 W/m², with corresponding water mass flow rates ranging from 0.0083 to 0.033 kg/s. The inlet water temperature was fixed at 15°C. The results demonstrate that increasing the coolant flow rate significantly reduces the PV surface temperature, thereby improving electrical efficiency, while higher solar radiation enhances thermal energy output. The study confirms that the integration of a heat collector and reflectors improves both thermal and electrical performance of the PVT system. A balance between radiation intensity and cooling conditions is essential to maintain PV operating temperatures within optimal limits. The modeling results are consistent with experimental observations, validating the effectiveness of the proposed approach for optimizing PVT system design.

1 INTRODUCTION

The installed solar power capacity in the world energy sector is increasing year by year and will exceed 1.4 TW in 2023, with China (609 GW) having the best performance. Renewable energy capacity is expected to increase to 473 GW (+13.9%) in 2023, with solar power accounting for 346 GW (+32.2%), followed by wind power with 116 GW (+12.9%) [1] (Figure 1).

The increasing efficiency of solar cells in converting solar energy into electricity is also driving the widespread use of this type of energy devices [2] (Figure 2).

Cooling PV (Photovoltaic Panel) panels, which convert solar energy directly into electricity, is considered effective in preventing the electrical efficiency from decreasing under the influence of high temperatures [3]-[7]. This cooling can consist of active, passive, or hybrid cooling systems [8]-[10]. A device equipped with such a cooling system is called a PVT (photovoltaic-thermal). The main purpose of such devices is to ensure that the PV electrical efficiency does not decrease due to temperature and to obtain additional thermal energy [11]-[15].

The part that extracts the heat is called the heat collector (HC). The more heat-conducting material that is attached to the PV surface, the more thermally and electrically efficient the device will be.

Modeling the physical processes occurring in PVT devices is also an important area [16]-[20]. Modeling is commonly used to analyze expected results without constructing an experimental device [21], [22]. In modeling, it is usually necessary to make some simplifications and specify initial conditions depending on the purpose [23]-[25].

Analytical formulations describing the energy balance and thermal characteristics of different components of PVT systems were reported in [26]. Several studies have also addressed the hydrodynamic behavior of PVT systems [27]-[28], alongside mathematical modeling approaches that

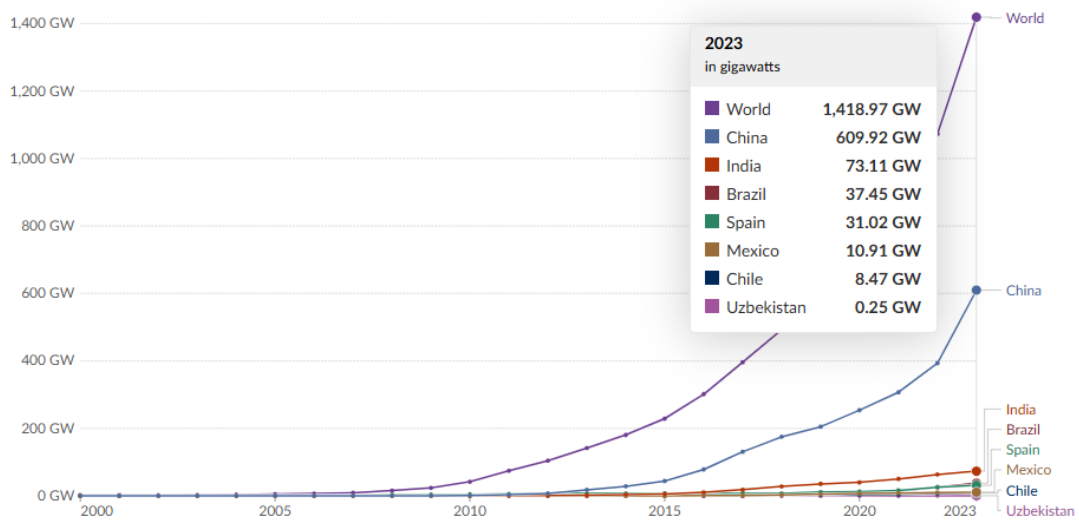

Figure 1: Installed solar energy capacity from 2000 to 2023

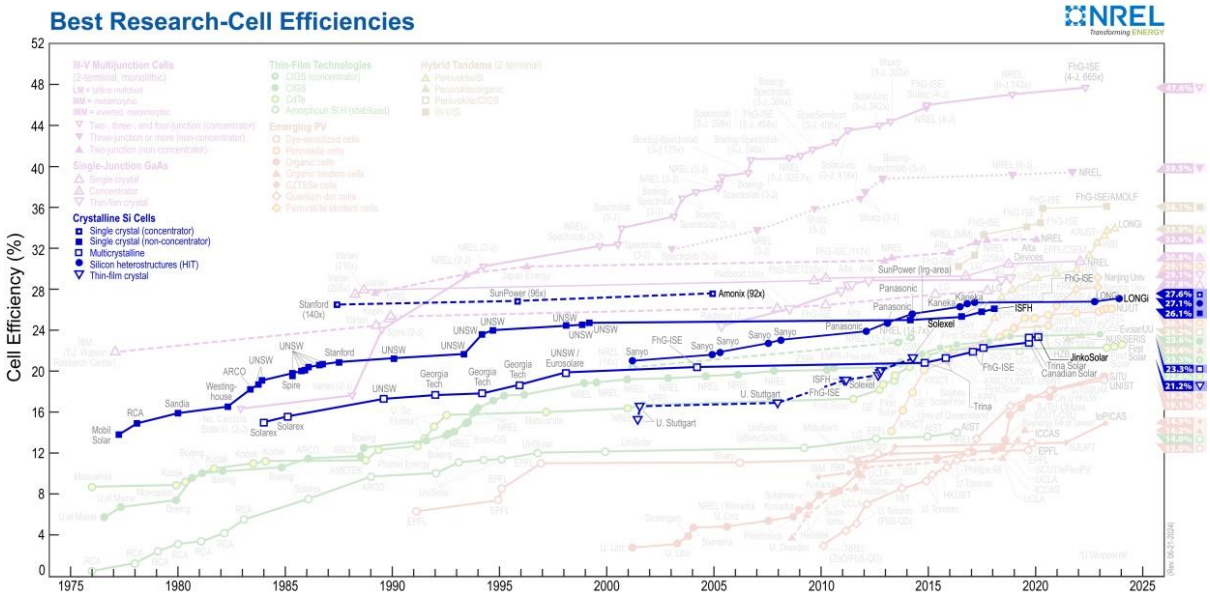

Figure 2: Crystalline silicon module efficiency

evaluate their electrical and thermal performance [29], [30]. Since solar energy represents a more sustainable option compared to other renewable sources, research in this field remains highly significant. This study focuses on analyzing the variation of thermal parameters in PVT systems through mathematical modeling.

Since we have already covered the practical part of our work in our previous work, let's focus only on the part based on the results obtained in the Comsole Multiphysics program.

2 METHODS AND MATERIALS

An overview of the main PVT device of the experiment is shown in Figure 3. The main function of reflectors is to increase the solar energy density and increase the thermal energy efficiency of the device. The water passing through the heat collector ensures that the PV panel temperature does not exceed the set point. These two aspects were taken into account in the modeling, and results were obtained for different values of solar radiation falling on the surface of the PV panel and water

mass flow. A monocrystalline silicon PV module with a maximum output power of 60 W was employed in the device. The specifications of the PV panel, along with the corresponding PVT system parameters derived from it, are summarized in Table 1.

Table 1: Geometric dimensions, physical and technical characteristics of PVT parts.

Parameters	Dimension
Geometric dimensions	
PV surface, S_{PV}	0.36m^2
PV frame width, d	2.5sm
Reflector surface, S_{ref}	0.36m^2
Reflector thickness, d_{ref}	0.4sm
The surface of the back cover, S_q	0.36m^2
The thickness of the back cover, d_q	0.4sm
Physical and technical characteristics	
Maximum power of PV, P_{max}	60W
Electrical efficiency of PV, η	16.5%
Open circuit voltage of PV, U_{oc}	24.4V
Short circuit current of PV, I_{sc}	3.33A
The fill factor of the PV's volt-ampere characteristic, FF	0.74
Reflection coefficient of the reflector, R	0.5
Water capacity of the heat collector,V	9 litre

The modeling studied the temperature distributions on the back surface of the panel, which are observed as a result of the effects of the heat collector and reflector of this device.

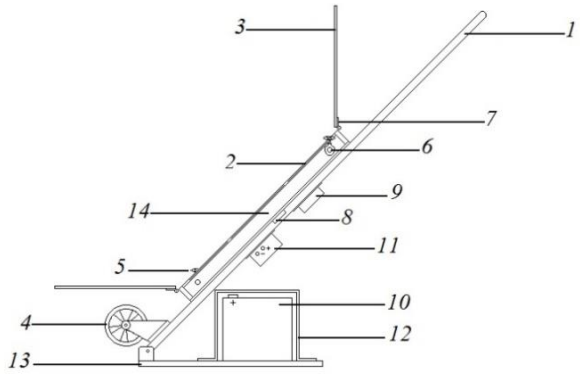

Figure 3: General view of the PVT device:

1 – structure handle, 2 – PV, 3 – reflectors, 4 – wheels of a small portable structure, 5, 6 – taps, 7 – hinges, 8 – positive and negative terminals of the electrical output of the PV, 9 – controller, 10 – battery, 11 – inverter, 12 – battery box, 13 – base of a small portable structure, 14 – heat collector.

The modeling was performed in the COMSOL Multiphysics 6.0 integrated software environment in the following sequence. After entering the program, the "Model Wizard" → "3D" sections were selected. To describe the heat exchange of water flow and the amount of heat absorbed in the PV with moving water in the HC, the "Laminar Flow (spf)" and "Heat Transfer in Solids and Fluids (ht)" interfaces were connected via the "Nonisothermal Flow" multiphysics interface. For the process under study, a new file with the extension ".mph" was created by selecting the "General Studies" → "Stationary" → "Done" sections.

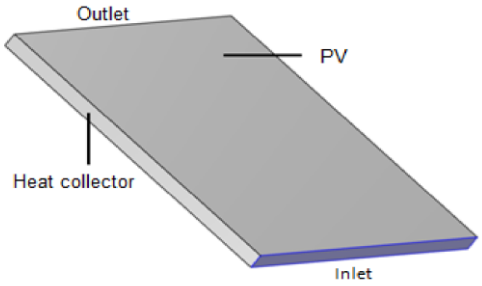

Figure 4: Part of PVT extracted for mathematical modelling.

The dimensions and parameters of the required geometric parts are selected through the "Model Builder" → "Component" → "Geometry" → "Block" sections, and the model geometry to be created through the "Build All Objects" section is displayed in 3D in the "Graphics" window. "The values of the variables and their units were described in the "Model Builder" → "Definition" → "Variables" sections. Through the "Definition" → "Selection" → "Explicit" sections, boundaries such as "Inlet", "Outlet", "Heat wall", and "Wall" were created and linked to variable values.

Using the "Model Builder" → "Materials" sections, "water" was selected from the material library as the cooling fluid. In this case, the values of all physical quantities for water are automatically loaded into the model.

Values such as "Inlet", "Outlet", "Wall" were created from the "Model Builder" → "Laminar Flow (spf)" section, and the lower part was selected for the "Inlet" section, considering that water moves from bottom to top. The water flow for the inlet section was expressed in kg/s. The upper boundary was selected for the "Outlet" section. The two sides and the back were defined as the boundary as thermal insulation and the front as the heat source passing through the back surface of the PV.

The energy density flux value for the heat source in W/m^2 is entered in the parameter-dependent state through the "Model Builder" → "Heat Transfer in Fluids" → "Heat Flux" sections. During the calculation of the results, the parameter values were changed, resulting in different results.

The "Model Builder" → "Multiphysics" → "Mesh" sections were selected, and the "Normal" section was selected for the "Element size". The model mesh part was created through the "Build All" section (Figure 5).

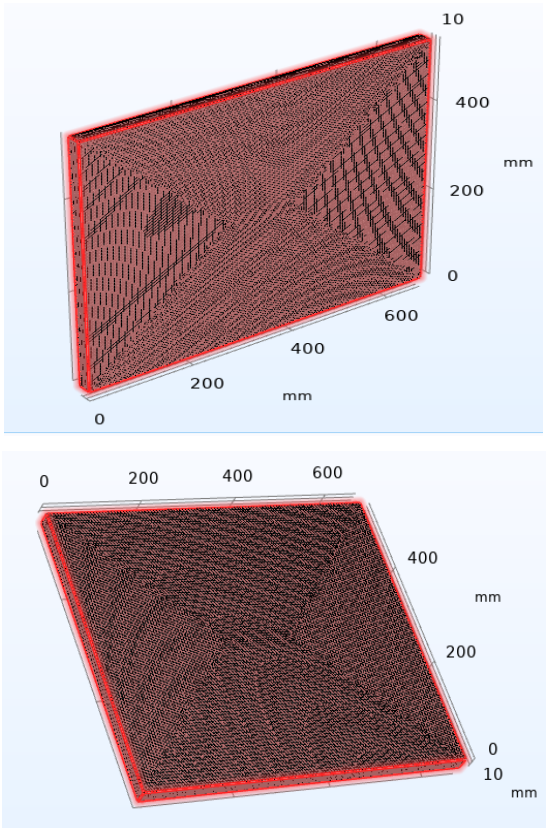

Figure 5: General condition of the mesh part

In the modeling process, the stationary Navier-Stokes equation was used in the blog through nonlocal connections and solved together with the continuity equation:

$$\rho(u\cdot\nabla)u = \nabla\cdot\left[-pI + K\right] + F \quad (1)$$

$$\rho\nabla\cdot u = 0 \quad (2)$$

Here ρ is the density of water (kg/m3), u is the flow velocity (m/s), I is the momentum (kg·m/s), K is the kinetic energy (J), and F is the external force (N).

The boundary conditions are set as follows:

- The fluid does not slip on the walls (boundaries) of the HC, i.e. u=0, the flow velocity is zero;
- The velocity of the liquid entering the HC is directed along the normal to the entrance surface;
- The pressure difference at the outlet from the HC is zero.

The "Heat Transfer in Fluids" interface was used for HC and PV heat transfer. The following heat balance equation for solids and heat transfer equations between layers were solved:

$$\rho c_p u\nabla T + \nabla q = \sum Q_i \quad (3)$$

$$q = -k\nabla T \quad (4)$$

where, u is the velocity of water (m/s), cp is the heat capacity (J/(kg°C)), q is the heat flux density (W/m^2), k is the heat transfer coefficient (W/(m^2°C))

3 RESULTS AND DISCUSSION

In the modeling, several suitable values of water consumption entering the cooling system, determined in the experiment, were entered and the results were obtained (Figure 6). It is estimated that 0.9 part of the total solar energy falling on the surface of the PV is completely absorbed, of which 0.75 part is spent on thermal energy, 0.15 part on electrical energy, and 10% on various heat and electrical losses. In this case, the portion of the 1500 W/m^2 solar radiation falling on the PV surface that is converted into thermal energy is equal to 1015 W/m^2, and in the calculations, the back surface of the PV was considered as a source of thermal energy. The initial temperature of the incoming water was taken as 15^{o}C (~288.15K). Figure 6 shows the results for water consumption values of a) 0.0083 (kg/s), b) 0.0167 (kg/s), c) 0.025 (kg/s), and d) 0.033 (kg/s). The HC boundary assumes a value of 1015 W/m^2 for the energy flux density as a heat source. The ambient temperature is assumed to be 15^{0}C (288.15K). From the graphs, the PV back surface temperature decreases as water consumption increases.

In the modeling, the water temperature at the back surface of the PV and the HC for different values of solar radiation incident on the PV surface, with the water consumption constant (0.01667 kg/s), is given in Figure 7.

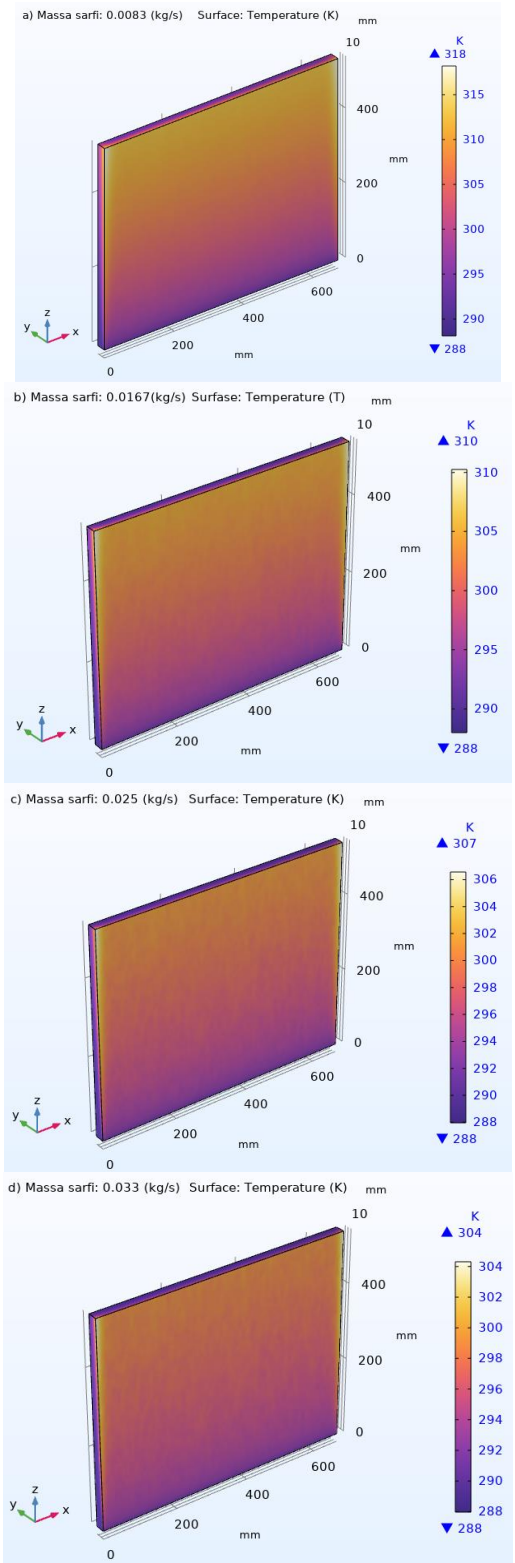

Figure 6. Temperature of the back surface of the PV at different values of water consumption entering the HC

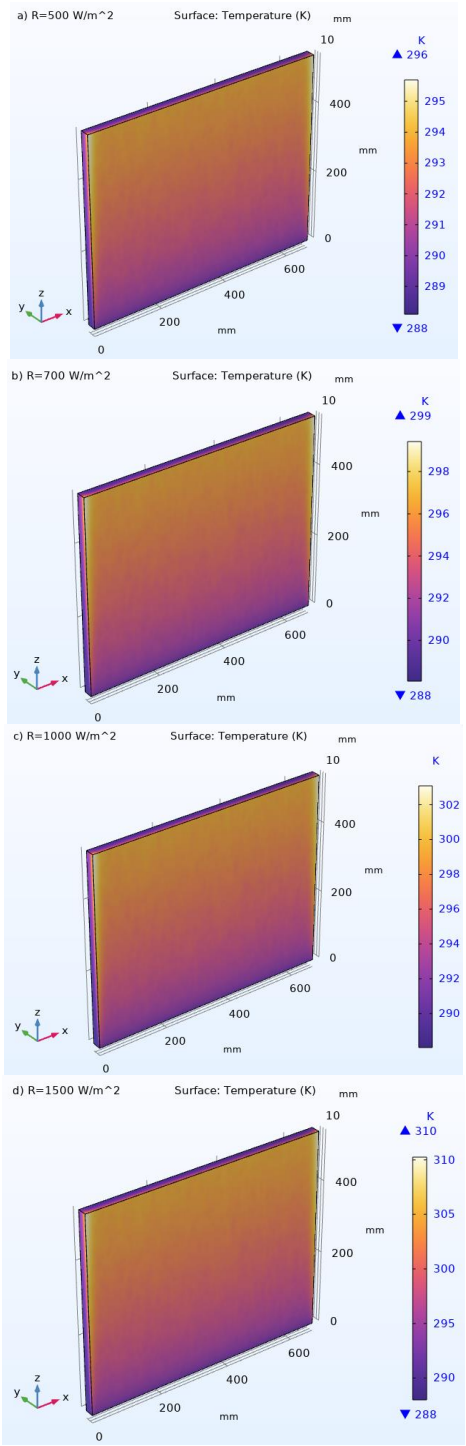

Figure 7: Surface temperature distribution at different values of radiation incident on the PV surface (water consumption (0.01667 kg/s)).

The results were obtained for the cases where the solar radiation incident on the PV surface was a) 500 W/m^2 b) 700 W/m^2 c) 1000 W/m^2 and

d) 1500 W/m^2. As solar radiation values increased, the PV back surface and outlet water temperatures increased steadily

Higher outlet water temperatures will inevitably lead to an increase in thermal energy. However, at the same time, this situation should not negatively affect the electrical parameters of the PV. The modeling results show that the maximum difference in PV rear surface temperatures was 37^{0}C (1500 W/m^2). The fact that the PV temperature is less than 60 ^{0}C is the basis for lower electrical losses due to its temperature.

At a simulated solar radiation value of 500 W/m^2, temperature differences are very small, with a value of 8^{0}C recorded. At these values, the efficiency of thermal energy utilization decreases sharply. For this purpose, it should be noted that reflectors serve as a key component for increasing the solar energy density. Increasing radiation increases the thermal efficiency of the system. However, increasing radiation values also requires consideration of PV temperature limits.

In the results obtained under natural conditions, the difference in water temperatures at the inlet and outlet was 5-30^{0}C. In this case, the water consumption and radiation values at the inlet were within the range of values used in the modeling. Therefore, the modeling and simulation results are consistent with the results obtained in real-world experiments.

4 CONCLUSIONS

The heat distribution on the PV surface and the temperature of the hot water that can be obtained from the heat collector are important. Through programming work performed in the Comsole multiphysics program, the heat distribution on the surface was studied at different values of radiation and water consumption. The graphs confirm that the temperature of the water leaving the HC reaches 30^{o}C with a maximum radiation of 1500W/m^2 and a water consumption of 0.0083kg/s. The modeling results show that at a water consumption of 0.017 kg/s, the temperature difference between the incoming and outgoing water is up to 20oC, and thus the temperatures on the PV surface are also maintained within this temperature range. This is the basis for improving electrical and thermal efficiencies by simultaneously increasing and cooling the incident radiation

Keywords: Outdoor Air Temperature, GTU, Compressor, Output Power, Efficiency.

Abstract: This study investigates the impact of ambient air parameters on the performance of a gas turbine unit (GTU) and evaluates methods for improving its efficiency through compressor inlet air cooling. Particular attention is given to the climatic conditions of Uzbekistan, where ambient temperatures vary widely from –25 °C to +45 °C, significantly affecting GTU operation. The analysis demonstrates that increasing ambient air temperature reduces air density, leading to a decrease in mass flow rate through the compressor and, consequently, a reduction in power output and overall efficiency. Based on ISO standard conditions (15 °C, 60% relative humidity), it is shown that a temperature increase of 10 °C results in an approximate 8% decrease in GTU power. Mathematical relationships describing the dependence of power and efficiency on inlet air temperature are derived and applied to the GTU operating at the Tashkent CHP plant. Three air cooling methods - absorption chillers, natural evaporative cooling, and forced evaporative cooling - are comparatively analyzed. The results indicate that, considering both technical and economic factors, forced evaporative cooling is the most practical and cost-effective solution. The proposed approach enables mitigation of performance losses and enhances the operational efficiency of GTUs under high-temperature conditions.

1 INTRODUCTION

According to ISO (International Organization for Standardization), for gas turbine units (GTUs), the standard outdoor air temperature is set at 15°C with a relative humidity of 60% and the GTU located at sea level. The rated power is determined under these standard conditions, leading to the following conclusions [1]:

- GTU performance increases as temperature decreases: For every 10°C drop in temperature below 15°C, the output power increases by 8% of the rated power. Conversely, for every 10°C rise in temperature above 15°C, the output power decreases by 8% of the rated power.
- The location of the GTU affects its power output: For every 300 meters above sea level, the output power decreases by 3.5%.
- Pressure losses in the system reduce power output: Exhaust gas pressure drops in filters, silencers, and outlet ducts amounting to 1 kPa cause a 2% decrease in output power.
- When the air temperature falls below 15°C, the GTU's power output correspondingly exceeds the rated value. However, the temperature of the air supplied to the compressor must not fall below 6°C. Below this temperature, water droplets in the air may turn into ice, which can enter the airflow path and cause damage to the equipment.

2 MATERIALS AND METHODS

For the model of the GTU at the Tashkent CHP Plant - 310TB95-977. The GTU was manufactured by HITACHI and has the following nominal operating parameters [2] (Table 1).

Table 1: Technical characteristics of the GTU at the Tashkent CHP Plant under nominal operating conditions.

Parameter	Value
Outdoor air temperature, °C	15
Ambient pressure, kPa	101.3
Operating load, %	100
Generator power output, MW	28.63
Thermal output for consumers as hot steam, MW	45.09
Total plant output, MW	73.72
Gas consumption, t/h	49.79
Gross efficiency, %	74.13

3 RESULTS AND DISCUSSIONS

A change in the outdoor air temperature T_1 at a constant gas temperature in front of the turbine T_3 leads to an increase in the power and rotational speed of the gas turbine unit (GTU), as well as an increase in the unit's output as T_1 decreases. At the same time, the efficiency of the unit also increases. Conversely, an increase in T_1 causes a decrease in the power and rotational speed of the GTU. Achieving the rated power of the GTU is only possible by increasing the gas temperature in front of the turbine above the design level.

The high sensitivity of gas turbine units to changes in outdoor air temperature at the inlet of the axial compressor is due to two main factors. First, many modern GTUs have fixed flow areas of the gas turbine and axial compressor, which eliminates the possibility of regulating air flow while keeping the working fluid parameters constant. Second, modern units are characterized by a significant ratio of compression to expansion work, equal to $\lambda = \frac{h_K}{h_T} = 0.6 - 0.7$ in the nominal operating mode and $\lambda \approx 0.80$ under partial loads [3].

The influence of changes in the cycle's extreme temperatures on the characteristics of the gas turbine unit can be analyzed by studying the following relationships.

As known, the indicated power of a gas turbine unit (GTU) is determined by the following relationship:

$$N_i = N_{ik} - N_{iT}, \tag{1}$$

$$N_i = G_t C_{pm} T_1 \left(1 - \frac{T_3}{T_1}\right) - G_k C_{pm} T_1 \left(\frac{T_2}{T_1} - 1\right), \tag{2}$$

$$N_i = N_{ik} \cdot \frac{\lambda - 1}{\lambda}, \tag{3}$$

$$N_i = f(\theta, n, \pi_k) = f_1(\theta, n), \tag{4}$$

$$\theta = \frac{T_2}{T_1}, \qquad \pi_k = \frac{p_2}{p_1}, \tag{5}$$

where θ is the cycle boundary temperature ratio; n is the rotational speed of the GTU shaft; π_k is the compression pressure ratio across the axial compressor.

The above relationships show that the power of the GTU largely depends on the cycle boundary temperature ratio. The increment in GTU power for small deviations of the cycle boundary temperature ratio (Δθ) from the nominal value (θ_0) at a constant rotational speed (n = idem) is equal to:

$$\Delta N_i = \frac{\partial N_i}{\partial \theta} \cdot \Delta\theta. \tag{6}$$

At the same time, the change in the cycle boundary temperature ratio (Δθ) will vary depending on changes in each of the cycle boundary temperatures (T_1 and T_3):

$$T_1 = idem; \qquad \frac{\partial \theta}{\partial T_1} = \frac{1}{T_1}, \tag{7}$$

$$T_2 = idem; \qquad \frac{\partial \theta}{\partial T_1} = -\frac{\theta}{T_1}. \tag{8}$$

Therefore:

$$\frac{\partial \theta}{\partial T_1} = -\theta \frac{\partial \theta}{\partial T_3}, \tag{9}$$

$$\frac{\partial N_i}{\partial T_1} = -\theta \frac{\partial N_i}{\partial T_3}. \tag{10}$$

It follows from relation (10) that for any values of □ₖ, |ᵢ,ₖ, |ᵢ,ₜ even a very small change in outdoor air temperature (T_1) can cause a change in GTU power several times greater than a change in gas temperature before the turbine (T_3).

To derive a calculated relationship for determining the change in unit power solely due to changes in outdoor air temperature, we adopt a number of simplifying assumptions: constant values of the relative efficiencies of the compressor and turbine, constant pressure ratios, constant gas temperature before the turbine, and constant working fluid flow rate through the unit. Only the outdoor air temperature changes. From (1):

$$\lambda = \frac{N_{ik}}{N_{iT}} \approx \frac{T_1}{T_3}, \tag{11}$$

$$\lambda_0 = \left(\frac{N_{ik}}{N_{iT}}\right)_0 \approx \frac{T_0}{T_3}, \tag{12}$$

$$\lambda = \lambda_0 \left(\frac{T_1}{T_0}\right), \tag{13}$$

where T_1 is the current value of the initial absolute outdoor air temperature; T_0 is the initial (design) value of the air temperature under nominal operating conditions (T_0 = 288.2 K); λ_0 is the power ratio of the compressor and gas turbine under the design operating mode of the gas turbine unit.

The specific power of the gas turbine as a whole can be considered independent of the outdoor air temperature at the compressor inlet. However, the compressor's output is directly dependent on the ambient air temperature, provided that the volumetric capacity of the compressor and the outdoor air pressure remain constant.

$$\frac{N_{e,T}}{N_{e,T,0}} \approx \frac{G_k}{G_{k.0}} = \frac{T_1}{T_0} \approx 1 - \frac{\Delta t_1}{T_0}. \quad (14)$$

From the relationship, (12) and (13) [4],

$$N_e = N_{e,T} - N_{e,k} = N_{e,T}(1 - \lambda), \quad (15)$$

$$N_e = N_{e,T,0}\left(1 - \frac{\Delta t_1}{T_0}\right)\left(1 - \lambda_0\left(\frac{T_1}{T_0}\right)\right). \quad (16)$$

In particular, for the nominal operating mode,

$$N_{e.0} = N_{e,T,0}(1 - \lambda_0). \quad (17)$$

From the relationship, (16) and (17),

$$\frac{N_e}{N_{e.0}} = \frac{\left(\frac{T_1}{T_0}\right)\left(1 - \lambda_0\left(\frac{T_1}{T_0}\right)\right)}{1 - \lambda_0}. \quad (18)$$

From the (16) and (17) the power ratio of the axial compressor and gas turbine under nominal operating conditions is typically $\lambda_0 \approx 0.65$. For the nominal operating mode of the Tashkent CHP GTU, $T_0 \approx 288$ K, and $N_{e.0}$ = 27 MW. Thus, we obtain the dependence of the Tashkent CHP GTU power on outdoor air temperature:

$$N_e(T_1) = 986{,}21 \cdot T_1 \cdot (288 - 0{,}65 \cdot T_1) \quad (19)$$

The reduced efficiency of the unit is related to the change in the relative power of the GTU by the ratio:

$$\frac{\eta_e}{\eta_{e.0}} = \frac{\frac{N_e}{N_{e.0}}}{1 - 0.75\left(1 - \frac{N_e}{N_{e.0}}\right)}. \quad (20)$$

For the nominal operating mode of the Tashkent CHP GTU, $T_0 \approx 288$ K, $\eta_{e.0} = 0.46$. From relations (19) and (20), we obtain the dependence of the Tashkent CHP GTU efficiency on the outdoor air temperature:

$$\eta_e = \frac{1481{,}6T_1(288 - 0{,}65T_1) \cdot 10^{-4}}{2863 + 2{,}96T_1(288 - 0{,}65T_1)}. \quad (21)$$

Using Eqs. (19) and (21), we obtain the dependence of the efficiency and power of the Tashkent CHP GTU on the outdoor air temperature, as shown in Figure 1.

During summer, when the outdoor air temperature reaches +45°C, the power output of the Tashkent CHP GTU decreases by 11% compared to the nominal operating mode (equivalent to 3 MW), while its efficiency decreases by 3%.

We propose three methods for cooling the air at the intake of the GTU compressor:

- Absorption chillers (ABHM);
- Natural evaporative cooling systems (NECS);
- Forced evaporative cooling systems (FECS).

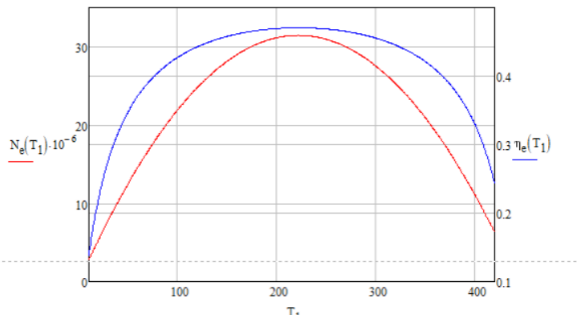

Figure 1: Dependence of the Tashkent CHP GTU power and efficiency on outdoor air temperature.

3.1 Absorption Chillers (ABHM)

One option for cooling the outdoor air supplied to the GTU compressor is the use of absorption chillers (ABHM). The operating principle of ABHM is based on the ability of a lithium bromide solution to absorb water vapor. The cooled medium enters the evaporator, where it is cooled to the required temperature by the evaporation of the refrigerant (water) under vacuum. Water vapor from the evaporator enters the absorber, where it is absorbed by the aqueous lithium bromide solution. The diluted (weak) solution is fed into the generator, where it is evaporated using an external heat source (hot water, steam, exhaust gases, or other types of secondary energy resources). The greater the required temperature reduction of the air before the compressor, the more heat must be supplied to evaporate water in the generator to obtain a larger amount of concentrated solution (e.g., LiBr). The heat source for the ABHM generator can be turbine or boiler steam, as well as hot water at temperatures of 150–180°C. [7] The saturated solution from the ABHM generator returns to the absorber. The water vapor generated in the condenser is condensed in the ABHM condenser. In some cases, the main condensate can be used as the cooling medium for the ABHM condenser before supplying it to the GPK KU. The evaporator operates under vacuum, causing water to boil at low temperatures. The deeper the vacuum, the lower the vaporization temperature. Water vapor enters the absorber. In the absorber, the concentrated lithium bromide (LiBr) solution, being a strong absorbent of water, absorbs the vapor, turning into a diluted solution, which is pumped back to the generator [8]. The operating principle of ABHM is shown in Figure 2.

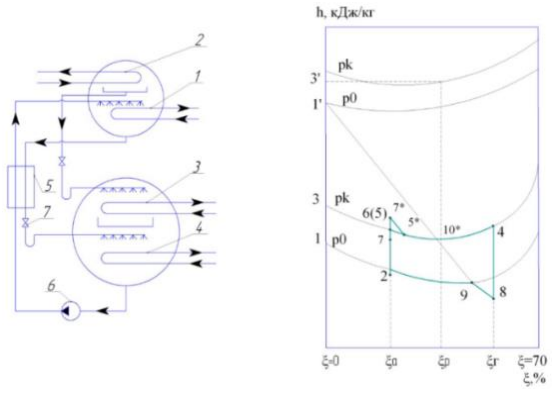

Figure 2: Schematic and cycle of a single-stage lithium bromide absorption chiller (ABHM): 1 – Generator;2 – Condenser; 3 – Evaporator; 4 – Absorber; 5 –Regenerative heat exchanger; 6 – Circulation pump; 7 – Throttle valve.

ABHMs require extended installation times and highly qualified personnel for both maintenance and repairs. Additionally, there is a risk of leaks of refrigerant harmful to human health [9]. The designed absorption chiller unit for the Tashkent CHP plant is shown in Figure 3.

A gas turbine power plant operates with a constant flow of outdoor air. When the temperature of the air entering the GTPP (Gas Turbine Power Plant) increases [12], its density decreases, reducing the mass flow rate of air in the compressor, which leads to a drop in the power output of the GTPP. By installing a cooling heat exchanger integrated into an absorption chiller-based cooling system (ABHM), the temperature of the air supplied to the GTPP's heat engine was reduced in some cases from +40°C to +15°C, resulting in an increase of electric power generation by approximately 30%. The process flow diagram of ABHM connection to the GTU is shown in Figure 4.

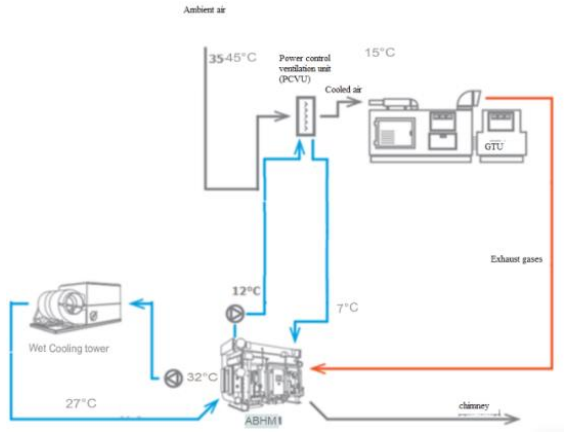

Figure 3: Schematic diagram of the designed absorption chiller unit (ABHM) at the Tashkent CHP plant.

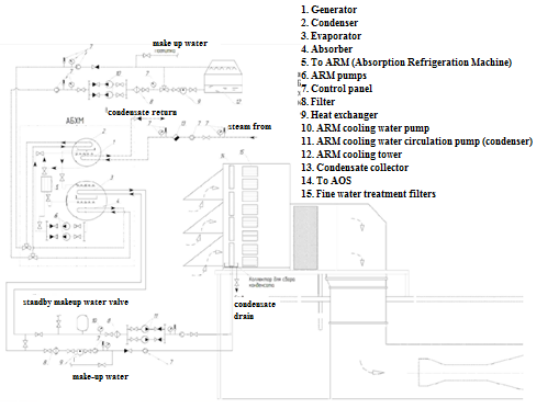

Figure 4: Process flow diagram of ABHM connection to the GTU [5].

Advantages [10]:

1) Highest cooling capacity (down to +12.5°C).
2) Ability to bypass the dew point of outdoor air during the cooling process.
3) Theoretical possibility of utilizing condensate generated during air cooling.
4) Extremely low makeup water consumption for the internal cooling circuit.

Disadvantages:

1) Highest technical complexity of system implementation.
2) Highest cost of the technical solution. The specific cost of ABHM at current prices ranges from 120–180 USD/kW, excluding the cost of the cooling tower and auxiliary equipment.
3) Significant space required for new equipment.
4) Necessity to create an independent water circulation circuit.
5) Significant expansion of the auxiliary equipment area required.
6) Annual maintenance by certified specialists and winterization are necessary.

3.2 Forced Evaporative Cooling Systems (FECS)

The operating principle of such systems is based on the physical phenomenon of air cooling through the evaporation of water droplets [11]. This method is most similar to the principle of natural evaporative cooling systems (NECS), with the key difference being that instead of passive water flow forming a thin film through which incoming air passes, nozzles are used to spray water and create fine droplets that subsequently evaporate. Forced evaporative cooling

uses a small amount of water injected at high pressure. Injection is provided at specific points in the air intake through specialized nozzles to create a cooling effect. Air cooling, in turn, reduces the energy consumed by the compressor drive.

Water droplets are generated by spraying water through nozzles. The efficiency of this system directly depends on droplet size. Minimal droplet size ensures an extensive heat and mass transfer surface between the water sprayed into droplets and the cooled air. During heat and mass transfer, water droplets evaporate, extracting thermal energy from the air. As evaporation occurs, air temperature decreases, while relative humidity and moisture content increase. It is important to note that the design goal of such a system is to supply an amount of water that ensures complete evaporation of all droplets. Any water droplets entering the compressor intake are unacceptable. In other words, the amount of water supplied for cooling is limited by the relative humidity of the cooled air. When relative humidity reaches 100%, the droplet evaporation process stops. Thus, the maximum achievable cooling is determined by the relative humidity and temperature of the air supplied to the FECS [6]. The nozzle layout of the FECS is shown in Figure 5. The process flow diagram of FECS connection to the GTU is shown in Figure 6.

Advantages:[13]

1) Relative simplicity of technical implementation.
2) Lowest equipment installation costs.
3) Minimal aerodynamic resistance.
4) Lowest weight load on the PCVU structure.
5) No complex maintenance required.

Disadvantages:

1) Cooling capacity is limited by the wet-bulb temperature.
2) Irreversible water carryover into the compressor.
3) Higher requirements for the droplet capture system.
4) Requires high-quality chemically purified water.
5) Short nozzle lifespan (approximately 2 years with regular use).

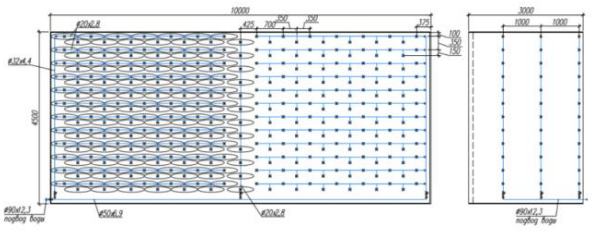

Figure 5: Nozzle layout diagram of the FECS.

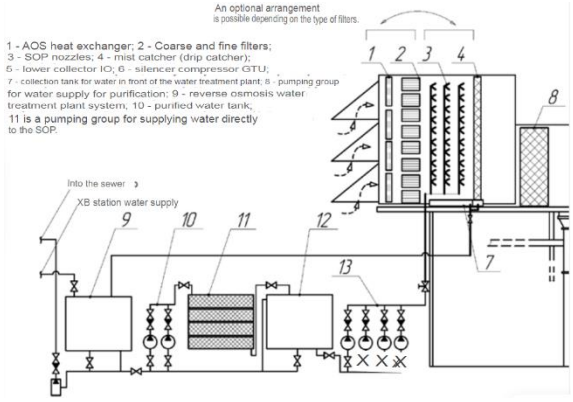

Figure 6: Process flow diagram of FECS connection to the GTU.

3.3 Natural Evaporative Cooling Systems

The essence of evaporative cooling is as follows. According to kinetic theory, water molecules are in random thermal motion, with their velocities varying widely [14]. Those molecules with the highest velocity (greatest kinetic energy) escape into the space above the water surface (evaporation). Only molecules near the water surface, whose velocity component normal to this surface is sufficiently high to overcome molecular attractive forces, can break away from the water. Water molecules that escape from the surface may collide with air molecules and be pushed back, resulting in condensation.

The practical implementation of this principle in gas turbine systems is realized through natural evaporative cooling systems (NECS), as shown in Figure 7, where the PCVU is combined with evaporative elements to reduce the inlet air temperature.

Furthermore, the process flow and integration of NECS into the combined cycle power plant (CCPP) configuration are presented in Figure 8.

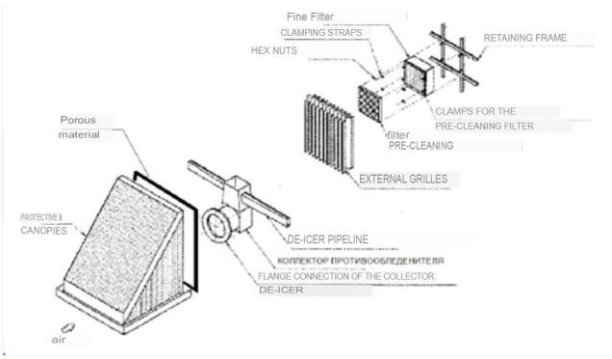

Figure 7: Diagram of the PCVU Combined with the NECS.

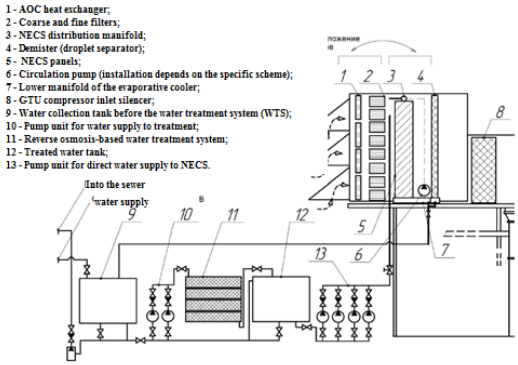

Figure 8: Process flow diagram of NECS connection to the CCPP systems.

Advantages:

1) Simplicity of technical implementation.
2) No complex maintenance required.
3) Water treatment requirements are less stringent compared to FECS.
4) Relatively easy dismantling of evaporative panels for winter (without GTU shutdown).
5) Auxiliary NECS equipment occupies minimal space. The installation does not create significant aerodynamic resistance in the PCVU pathway.

Disadvantages:

1) Cooling capacity is limited by the wet-bulb temperature.
2) Irreversible water carryover into the compressor.
3) Relatively high project implementation cost due to limited competition among manufacturers in this niche.
4) Higher requirements for the droplet capture system.
5) Scarcity of companies specializing in such projects.

4 CONCLUSIONS

This study examined the influence of ambient air temperature on the performance of a gas turbine unit (GTU) and evaluated practical methods for improving its efficiency under high-temperature conditions. The analysis confirmed that an increase in inlet air temperature leads to a decrease in air density, which reduces the mass flow rate through the compressor and results in a decline in both power output and overall efficiency of the GTU.

Based on the developed mathematical relationships, it was shown that the GTU operating at the Tashkent CHP plant experiences a noticeable performance drop at elevated temperatures, with power losses reaching up to 11% during peak summer conditions. This highlights the critical importance of inlet air cooling for maintaining stable and efficient operation.

A comparative assessment of three cooling methods - absorption chillers, natural evaporative cooling systems, and forced evaporative cooling systems - was conducted. The results indicate that while absorption chillers provide the highest cooling capacity, their implementation is associated with significant capital and operational costs. Natural evaporative systems offer a simpler solution but are limited in efficiency.

Among the considered options, forced evaporative cooling systems demonstrate the most favorable balance between technical effectiveness and economic feasibility. Their relatively simple design, low installation cost, and sufficient cooling performance make them the most practical solution for improving GTU efficiency under the climatic conditions of Uzbekistan.

Keywords: Channel, Spherical Dimples, Protrusions, Heat Transfer Surface, Flow Turbulization.

Abstract: This article presents the results of a study of heat transfer on surfaces with spherical depressions. It provides a rationale for the relevance of the study and a brief overview of previously conducted studies. It specifies the factors that affect the intensity of heat transfer, and explains the mechanism of flow turbulence in a channel with spherical depressions and protrusions. It displays data that determine the parameters that are directly or indirectly included in the similarity criteria, initial and boundary conditions, as well as the geometric and thermal characteristics necessary to create a mathematical model. The mathematical model of heat exchange in channels with an improved heat exchange surface with applied spherical depressions and protrusions is considered, allowing to estimate the influence of the presence of local turbulent areas on the channel surfaces on the Nusselt number in comparison with a similar channel with smooth surfaces. Also, the results of numerical studies on the influence of turbulence on heat exchange characteristics of channels with an improved heat exchange surface are presented in the form of graphs.

1 INTRODUCTION

One of the main tasks of heat engineering for many years remains the task of studying the flow of viscous liquid and heat exchange in channels with spherical depressions and protrusions applied to the heat exchange surface. The practical significance of these studies is associated with the intensification of heat exchange in surface heat exchangers.

One of the solutions for increasing the efficiency of heat-using equipment is to increase heat transfer (heat transfer) from one heat carrier to another. This goal is achieved by various methods and techniques. The most commonly used method is turbulization of the heat carrier flow. With turbulized flow of liquid or gas, heat transfer is much more intense than with laminar flow. Turbulization of the flow can be achieved by using various devices located on the heat exchange surfaces. Fins of various shapes, nozzles, artificial roughness and much more can be used as turbulators. It should be borne in mind that the use of turbulators, although it helps to increase the efficiency of heat transfer, leads to an increase in resistance, and therefore to an increase in the pressure drop of the flow.

2 MATERIALS AND METHODS

To intensify heat exchange in channels with flat heat exchange surfaces, a method of flow turbulization is often used by applying spherical and other forms of irregularities to the heat exchange surface [1]-[4].

The use of turbulizing surfaces in the form of various dimples and protrusions is one of the methods of intensifying heat exchange in narrow channels [5]-[7].

The flow and heat exchange modes in channels, especially in narrow channels with turbulizing surfaces, differ from similar processes occurring in smooth channels.

The main factor influencing the intensity of heat exchange in such channels is the presence of spherical

depressions and protrusions on the heat exchange surfaces, which serve to turbulize the flow.

When coolants flow around spherical depressions and protrusions located on the heat exchange surface, dynamic vortex structures arise, which are observed both in laminar and turbulent flow regimes. The resulting vortices contribute to an increase in heat transfer [8], [9].

When constructing a model and processing the experimental results in the form of criteria formulas, it is necessary to specify the determining parameters that are directly or indirectly included in the similarity criteria. In stationary problems of convective heat exchange, the determining parameters include:

- R_0 – determines (characteristic) size of the heat exchange region;
- T_0 – determines (characteristic) temperature in the heat exchange region;
- w_0 – determines velocity.

When creating a mathematical model of heat exchange on a surface with applied spherical depressions and protrusions, the geometric values of the depressions and protrusions were changed in the following ranges: h is the depth of the depression 0.1-20 mm; S_x is the longitudinal step, 10-50 mm; S_y is the transverse step, 5-35 mm; γ is the density of application of depressions and protrusions, 20-70%, and the thermophysical parameters of the flow took values in the following ranges: Re – 1000-50000; ν is the kinematic viscosity of flue gases 112x106 m^2/sec; ω_0 is the flow velocity of flue gases, 1-20 m/sec: *a* is the coefficient of thermal diffusivity of flue gases, = 183.2 m^2/sec, the geometric parameters of the channel were adopted as follows: d_k is the channel diameter, d_k= 4f/П; H – 30-60 mm; l – 35-85 mm; $d_л$ – recess diameter, 10-30 mm.

The modeling is based on numerical calculations based on the dependence proposed in [10], [11], [12]:

$$\frac{Nu}{Nu0} = (1+0{,}50\,\gamma)\,K_f\,, \qquad (1)$$

where $K_f = \pi h^2 / 2 S_x S_z$.

For a smooth surface, heat transfer is calculated using the following formula:

$$Nu_0 = 0.024\,Re_0^{\,0.8}\,Pr^{\,0}, \qquad (2)$$

where Pr = 0,61, criteria $Re_0 = \omega_0 d/\nu$.

Having determined Nu_0 from (1), we find Nu and then α, the heat transfer coefficient for the improved surface:

$$\alpha_1 = Nu\,\lambda_{gas} / d_к, \qquad (3)$$

where λ_{gas} = 8.27 10-2, W/m deg, is the thermal conductivity coefficient of flue gases at t_{gas} = 700°C. In addition, calculations were carried out using the empirical equation proposed in [12], where the channel height H is taken into account in the geometric coefficient.

$$\frac{Nu}{Nu_0} = 1 + 4{,}4\,[\gamma(h/D)]^{0,8}/(\frac{H}{D})^{0,6}\,, \qquad (4)$$

where H is the channel height, m.

The analysis of (1) and (4) showed that (1) does not take into account the depression diameter D, while (4) does not consider the density of the applied depressions γ. Considering the significance of the parameters D and γ, the authors proposed the following (5) for calculating the heat transfer intensity, which accounts for the influence of both of these parameters.

$$\frac{Nu}{Nu_o} = 1+ (\gamma\,K_{f1})/\,\mathrm{Nuo}, \qquad (5)$$

where $K_{f1} = (\pi(2hr - h^2))/(S_x\,S_z)$,
where r – radius of the depression, m.

3 RESULTS AND DISCUSSION

Numerical calculations for given geometric and thermophysical parameters yielded the following results, some of which are shown in Figure 1, Figure 2, Figure 3, Figure 4, Figure 5, Figure 6.

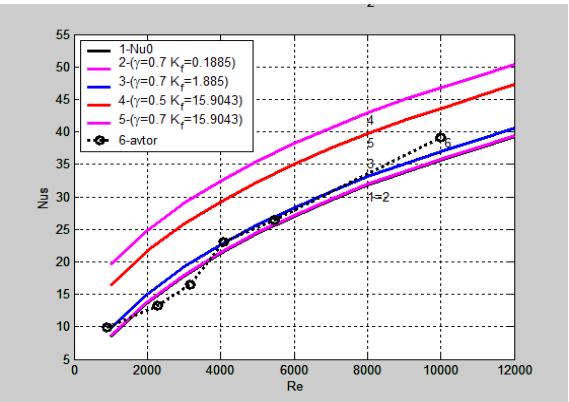

Figure 1: Dependence of the Nusselt number Nu on the Reynolds number Re at various values of γ.

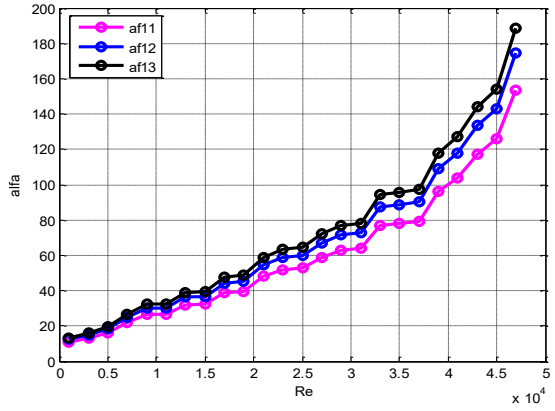

Figure 2: Dependence of the heat transfer coefficient α on the Reynolds number Re for different values of γ.

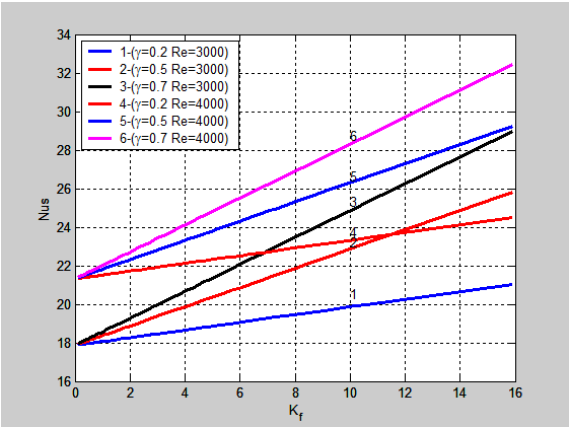

Figure 3: Dependence of the $\frac{Nu}{Nu0}$ ratio on the Reynolds number (Re) for different values of γ and dk.

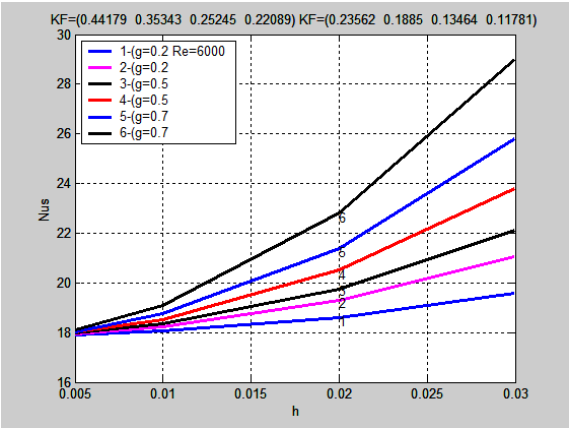

Figure 4: Graph of the dependence of $\frac{Nu}{Nu_0}$ on h, the dimple depth, at different dimple densities γm=0.2; 0.5; 0.7 and at various Kf values (Re= 6000).

Analysis of the obtained calculated curves showed that as the depth of the turbulence-inducing dimples and the area of the surface with such dimples increase, the intensity of heat transfer from the heat carrier to the surface also increases. A similar pattern of the influence of dimple depth on heat transfer intensity at different values of the improved (dimpled) surface area fraction is observed for various Reynolds numbers (Re).

The analysis of the calculated curves presented in Figure 4 shows that an increase in the density of turbulence-inducing dimples (g_m) leads to an increase in heat transfer intensity. Moreover, as the geometric coefficient Kf increases, the enhancement of heat transfer becomes more significant. It should be noted that the nature of the influence of dimple density on heat transfer intensity remains consistent for different Reynolds numbers (Re).

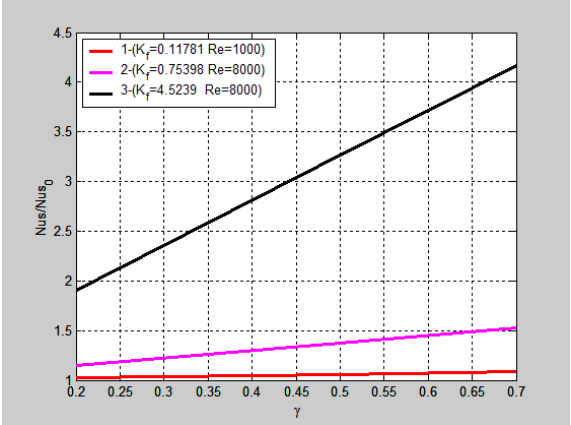

Figure 5: Dependence of $\frac{Nu}{Nu_0}$ on the dimple density γm at different values of Kf=0.11781, 0.7539, 4.5239 (Re= 1000, 8000).

Figure 6 presents graphs of the calculated values showing the influence of the geometric coefficient K_f on the intensity of heat transfer. The analysis showed that as the fraction of the surface improved with turbulence-inducing dimples increases, the heat transfer intensity also increases. An increase in the Reynolds number (Re) likewise leads to an increase in heat transfer intensity.

Special attention should be paid, when designing heat exchange surfaces with turbulizers, to the parameters of dimple arrangement on the surface — that is, to analyzing the influence of the longitudinal and transverse pitches of the dimples, which determine the dimple density coefficient. The influence of the arrangement parameters (transverse and longitudinal pitches) on the heat transfer intensity was investigated numerically (Figures 7 and 8).

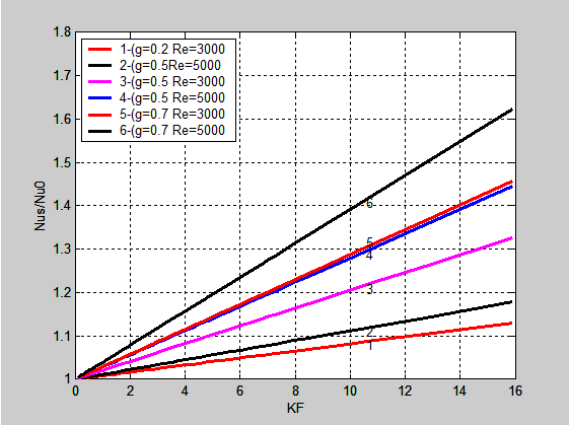

Figure 6: Graph of the dependence of heat transfer intensity $\frac{Nu}{Nu_0}$ on the geometric coefficient Kf at different dimple densities γ = 0.2; 0.5; 0.7 and Re = (3000, 5000).

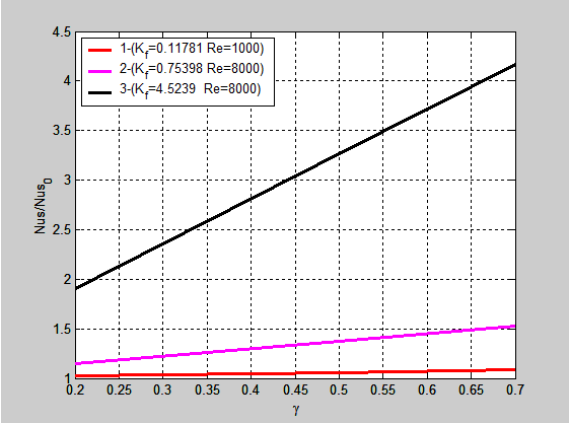

Figure 7: Graph of the dependence of $\frac{Nu}{Nu_0}$ o on Sz at γ = 0.2; 0.5; 0.7 and Re = 6000.

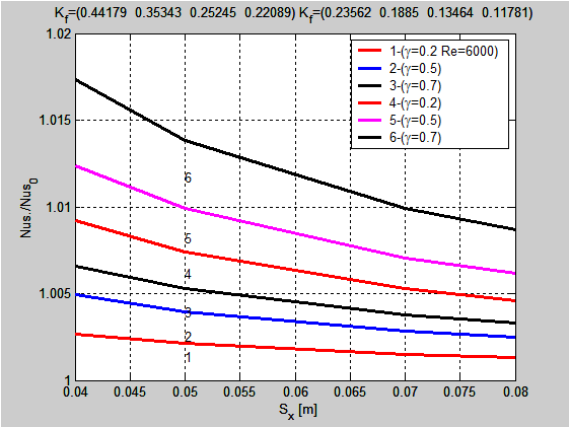

Figure 8: Graph of the dependence of $\frac{Nu}{Nu_0}$ on Sx at γ = 0.2, 0.5, 0.7 (Re = 6000).

The analysis showed that as the geometric parameters of the arrangement of turbulence-inducing depressions increase, the intensity of heat transfer decreases. This is due to the overall reduction of the geometric coefficient Kf and the decrease in the proportion of the enhanced surface.

The authors conducted a comparative analysis of the results obtained using the proposed (5) with the results of studies by other researchers [11], [12]. Figures 9, 10, and 11 present several graphs illustrating this comparative analysis.

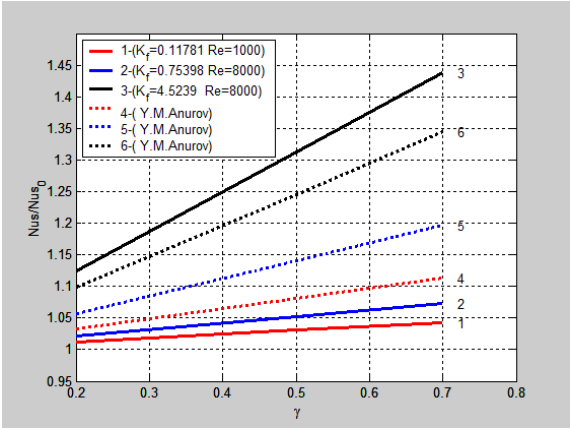

Figure 9: Dependence of the heat transfer intensity $\frac{Nu}{Nu_0}$ on the density of the applied depressions γ.

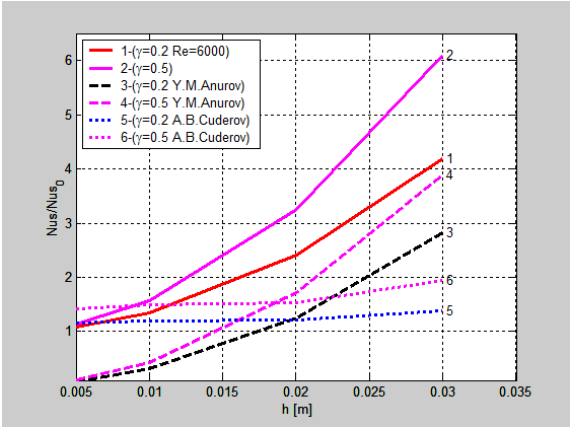

Figure 10: Dependence of the heat transfer intensity $\frac{Nu}{Nu_0}$ on the depth of the turbulence-inducing depressions h.

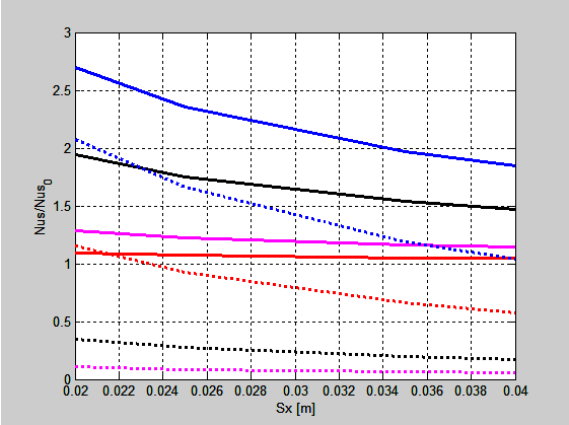

Figure 11: Dependence of the heat transfer intensity $\frac{Nu}{Nu_0}$ on the longitudinal pitch Sx of the depressions arrangement.

4 CONCLUSIONS

The analysis of the obtained dependencies showed that the flow turbulization achieved by applying turbulence-inducing depressions on the heat exchange surface enhances heat transfer. Increasing the depth of the turbulence-inducing depressions (h) together with the density of the applied depressions (γ) contributes to up to a twofold increase in heat transfer, although at certain S_x values, a slight decrease in heat transfer is observed.

An increase in the density of turbulence-inducing depressions at a constant geometric coefficient (K_f) also intensifies heat exchange, though to a lesser extent.

Changes in the geometric dimensions of the depressions likewise affect the heat transfer intensity; with larger dk values, large vortices form in the depression area, leading to a predictable increase in flow turbulence and consequently enhanced heat transfer. Overall, flow turbulization using depressions allows for an increase in heat exchange intensity, which in turn can reduce the initial consumption of organic fuel.

Abstract: The study addresses the utilization of low-pressure water sources for electricity generation as an important approach to ensuring sustainable energy supply in rural and remote areas. Conventional turbines experience high energy losses, frequent cavitation phenomena, and reduced service life under low-pressure conditions. To overcome these challenges, this research focuses on improving the internal guiding mechanism of a nozzle-type reactive micro-hydroturbine to enhance efficiency, minimize energy losses, and extend operational durability. The main objective is to design and develop a conical confusor-based internal guiding mechanism with optimized blades and to assess its influence on flow stability and efficiency through CFD modeling and experimental verification. The research employs a comprehensive methodology combining analytical analysis, mathematical modeling, and experimental testing. Bernoulli's equations were applied to determine flow velocity and energy losses, while CFD modeling was performed using COMSOL Multiphysics 6.1 software based on the RANS method with a k–ε turbulence model. Flow velocity and pressure distribution were analyzed, and a 500 W prototype of the hydroturbine was experimentally tested under 2–6 meters of water head on a specially designed laboratory stand. The results contribute to improving the performance and operational stability of micro-hydroturbines designed for low-pressure water sources, promoting the wider implementation of sustainable energy technologies in decentralized power systems.

1 INTRODUCTION

According to the International Energy Agency's 2024 report, the reserves of hydrocarbon fuels will historically last for a relatively short time; that is, if consumed at the current rate, natural gas and oil fuels are expected to last for 70–80 years, while coal may last for 150–200 years [1]. In this period of rapidly increasing global energy demand, saving underground fuel reserves and preventing environmental problems require the efficient use of all types of renewable energy sources to produce environmentally clean energy. Therefore, the effective utilization of existing low-head water resources in the field of hydropower, which is one of the renewable energy sources, can also contribute to solving the abovementioned issues. Electricity generation from low-head water resources, especially in rural and decentralized remote areas, can be considered both as a method of organizing power supply based on hydropower systems (rivers, irrigation canals, and small reservoirs) and as an ecological solution through the rational use of water resources. It is well known that when conventional turbines operate under low-head conditions, a number of problems arise. These include strong turbulence, uneven velocity distribution, cavitation, and significant energy losses due to local and hydraulic resistances, resulting in reduced turbine service life. In most hydroturbines, the efficiency does not exceed 70% [2]. Over the past decade, many researchers have worked on improving the performance of hydroturbines designed for low-head operation. This has been done by enhancing the runner wheels and guide vanes, optimizing the nozzle geometry in jet turbines, and improving the design of guide vane geometry [3]. In particular, studies on guide vane

control, turbulence reduction, cavitation mitigation, and overall efficiency improvement have been carried out. Hue L. et al. [4] emphasized that, under low-head conditions, the energy recovery efficiency with guide vanes could be improved by up to 3.11%. Bao Ngoc Tran et al. [5] found that, in guided vane configurations, a combination of eight vanes with a 30° inclination could increase efficiency by 6.3% and power output by 4.2%. Such modeling and CFD analysis results were also reported in the works of Ramalho, R. V. C. et al. [6] and Barsi, D. et al. [7], who showed that regulation of flow could improve hydraulic efficiency across a wide range of operating conditions. Chaulagain, R. K. et al. presented findings on the characteristics of existing turbines. In most cases, research results remain limited to CFD [8]; comprehensive methodologies combining analytical modeling, numerical simulations, and prototype testing have not been sufficiently applied. Furthermore, much of the literature is devoted to medium-scale systems of 20–500 kW, while compact prototypes below 5 kW have not been adequately studied. Yet, such systems are of crucial importance for rural agriculture and electrification of remote networks. Recent studies have analyzed, in detail, the influence of the number and shape of guide vanes as well as additional conical parts on hydraulic losses and overall energy performance using CFD software. For instance, Takamure et al. [9] investigated small hydroturbines with conical devices, determining torque and output power by comparing CFD and experimental results. Their findings confirmed the positive effect of diffusers on the flow process. Shi et al. [10], based on entropy theory, analyzed the effect of different guide vane numbers on energy losses, concluding that an increase in vane number leads to higher efficiency. Yang et al. [11] developed a novel "Split Sliding Guide Vane" (SSGV), which successfully eliminated leakages in the flow and improved system stability. Vijay Kumar et al. [12], by varying the opening degree of guide vanes in a Francis turbine, demonstrated that maximum efficiency depends on the opening angle (≈50.25%). This result provides a methodological basis for determining the turbine's optimal operating regime. Romero-Menko et al. [13] studied cross-flow turbines and showed that the shape and arrangement of internal elements and nozzle configuration significantly affect turbine efficiency. Similar results can be seen in other similar studies on low-head hydroturbines [14]-[17]. The literature review indicates that optimization of internal guide apparatus and CFD modeling contribute significantly to experimental validation. However, the application of conical diffusers and optimized vane geometries in jet hydroturbines has not yet been studied. The novelty of this research lies precisely in this aspect: the combined application of analytical modeling, CFD simulation, and experimental testing to justify the optimal parameters of a jet reaction turbine.

2 MATERIALS AND METHODS

The general scheme of the hydroturbine with an improved internal guiding structure is presented below (Fig. 1).

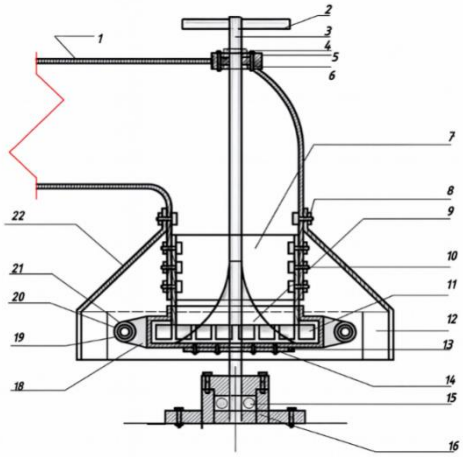

Figure 1: General scheme of the reaction hydroturbine with an improved internal guiding structure: 1 – water inlet channel; 2 – pulley; 3 – shaft; 4 – gland; 5 – bearing; 6 – bearing housing; 7 – supply cylinder of the improved internal guiding structure; 8 – stationary housing of the hydroturbine and fixing bolts; 9 – conical diffuser of the guide device; 10 – attachment bolts of the guide device to the supply pipe; 11 – guide vane profile; 12 – water-returning blades of the stator; 13 – runner cylinder; 14 – cylindrical base connecting the runner to the shaft; 15 – lower base bearing fixed to the dam; 16 – base bearing housing; 17 – platform; 18 – water inlet channel to the nozzle; 19 – nozzle working body; 20 – nozzle diffuser; 21 – water outlet channel and diffuser; 22 – stator of the hydroturbine.

The water flow, maintained at constant pressure in the reservoir, passes through supply pipe (1) into the supply cylinder (7) of the improved internal guiding structure. It then enters the gap between the central conical diffuser (9) and the supply cylinder, which gradually narrows towards the lower section. In this stage, the water flow, initially in the vertical direction, is smoothly redirected into the horizontally oriented guide vanes (11). During this transition, while the flow width remains constant, its direction changes

relative to the radial axis and acts upon the inner wall of the nozzle (18), which is fixed to the runner cylinder (13), at an optimized angle β = 15–18°.

At the nozzle inlet, the flow exerts pressure and active force on the inner surface. After reflecting from the inner wall of the nozzle, the water jet continues toward the diffuser section (20) of the outlet channel (19). The water jet exits the nozzle at high velocity in a compact stream, creating an impulse force in the opposite direction, which generates a reactive force on the nozzle. Consequently, the runner of the hydroturbine rotates in the opposite direction to the water jet. The outgoing jet strikes the vertically positioned stator blades (12) of the stator (22) perpendicularly, after which, under the influence of gravity and the inclination of the stator blades, the water falls downward and exits through the discharge channel. The rotary motion of the runner is transmitted to the generator via the shaft (3) connected to the pulley (2).

The motion of water inside the hydroturbine consists of several stages. Considering the energy loss due to nozzle type, a correction factor φ = 0.95 was introduced. The average velocity of water at the turbine inlet section (υ_1) was calculated using Bernoulli's equations, based on the mean flow velocity up to the entry point of the internal guiding structure vanes [17]:

$$\upsilon_2 = \sqrt{\frac{\frac{\rho Q \upsilon_1}{\gamma S_2}\left(\frac{S_1}{S_2}-1\right)+\frac{\alpha_1 \upsilon_1^2}{2g}-\sum h_{1i}+z_1-z_2}{\alpha_2}\cdot 2g}, \quad (1)$$

where F_d – cross-sectional area of water flow at the turbine inlet (minimum section); F – cross-sectional area of the supply pipe; υ_1 – average velocity at turbine inlet; Q – flow rate.

To analyze the motion of water through the internal guiding structure, the schematic diagram shown in Figure 2 was used.

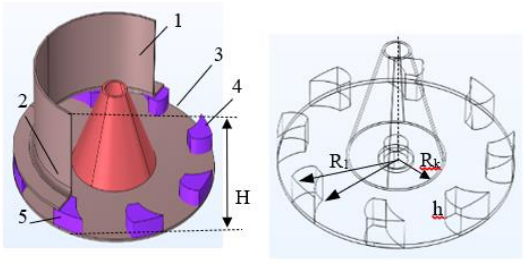

Figure 2: General schematic view of the improved internal guiding structure: 1 – supply cylinder; 2 – annular upper disc; 3 – lower disc; 4 – guide vanes; 5 – water outlet from the guiding structure.

Let υ_2 denote the average velocity of water exiting through the channels between discs (2) and (3). When the water is redirected from vertical to horizontal channels, energy losses occur due to the 90° turn and friction with the guide vanes. However, since vane dimensions are relatively small, frictional losses can be neglected. To ensure no energy loss when water flows from the supply cylinder to the nozzle, the cross-sectional area of the supply cylinder (S_2, with diameter d_2) must equal the total inlet area of the channels. The channels are placed symmetrically along the cylinder periphery. Assuming all dimensions are identical, the vane height H_k is determined by:

$$H_k = \frac{\pi d_2}{2k\varphi\alpha}, \quad (2)$$

$$\varphi = \frac{\alpha d_2 - \delta}{\alpha d_2}, \quad (3)$$

where k – number of vanes; φ – flow coefficient at vane entrance; α – central angle between adjacent vanes; δ – sum of vane thickness and blocked arc length for fixing.

Based on Zhukovsky's theory, the velocity of water exiting the guiding structure is given by:

$$\upsilon_3 = \upsilon_2\left(\frac{kl\sin\alpha_1}{d_2}+\cos(\alpha_2-\alpha_1)\right) \quad (4)$$

where l – vane length; α1, α2 – entry and exit angles of the guide vanes.

The total energy loss of the water flow in the turbine is determined as:

$$h_G = \left(\frac{S_1}{S_2}-1\right)^2\frac{\upsilon_1^2}{2g}+\xi_{90^\circ}(1-\cos\varphi_2)\frac{\upsilon_3^2}{2g}+\xi_{SK}\frac{\upsilon_3^2}{2g}+\left(\frac{S_3}{S_6}-1\right)^2\frac{\upsilon_4^2}{2g} \quad (5)$$

where ξ – hydraulic resistance coefficient; α – cone formation angle; ψ – proportionality coefficient (ψ = 2 for pipes, ψ = 1 for rectangular sections); λ – Darcy friction coefficient.

The torque and angular velocity of the runner were determined using the general theorem on the variation of angular momentum for a rigid body:

$$\omega_z = \frac{S_3\upsilon_3^2\left(\cos\beta+\sqrt{\frac{S_3}{S_6}\left(\frac{S_3}{S_6}-1\right)+1-\frac{1}{2}\left(\xi_{SK}+\xi_{90}\right)}\right)}{\pi r_c^3\upsilon_4}+\frac{\upsilon_4}{r_c}; \quad (6)$$

where r_c – distance from the rotation axis to nozzle center; υ_3, υ_4 – water velocities at nozzle inlet and outlet.

Table 1: Parameters introduced in mathematical modeling.

Name	Expression	Value	Description
dens	1000[kg/m^3]	1000 kg/m³	Water density
visc	8.9e-4[Pa*s]	1E−5 Pa·s	Dynamic viscosity of water
vs	6[m/s]	6 m/s	Water inlet velocity into the nozzle
Re	2*R1*vs*dens/visc		Reynolds number
Q	0,2[m^3/s]	0,2 m³/s	Water flow rate
H	2,5 [m]	2,5 m	Static head of water
omega z	6,6 [rad/s]	6,6 rad/s	Angular velocity of the runner
bm	0,004[m]	0,004 m	Thickness of the nozzle wall
alfa1	15[grad]	0,2618 rad	Water inlet angle to runner guide vane
alfa2	12[grad]	0,20944 rad	Water outlet angle from runner guide vane
betta	15[grad]	0,2618 rad	Installation angle of the guide vane relative to radial direction
lamb	0,05	0,05	Darcy friction coefficient
G	9,81[m/s^2]	9,81 m/s²	Gravitational acceleration
N	8	8	Number of guide vanes
fi_0	0,95	0,95	Water inlet coefficient
hi	15[grad]	0,2618 rad	Diffuser angle at nozzle outlet
R_1	(Q/(3,14*fi0*(2*g*H)^0,5))^0,5	0,10346 m	Inlet pipe radius to hydroturbine
R_2	0,98*R1	0,10139 m	Radius of supply cylinder in guiding device
myu	S3/S4	3	Ratio of inlet to outlet areas of nozzle
delta	0,02[m]	0,02 m	Distance between runner cylinder and guide vane
Hk	0,026[m]	0,026 m	Radial height of the guide vane
m	4	4	Number of nozzles
Rs	Hk + delta + bm + R2	0,15139 m	Distance from runner center to nozzle
p	10	10	Percentage of circle occupied by nozzle fixing
alfa	2*pi/m*n[deg]	0,21932 rad	Nozzle occupied angle
v_2	(fi0/R2^2)*(2*g*H*(R1^4 - R1^2*R2^2 + R2^4))^0,5	6,0774 m/s	Velocity of water at guide vane inlet
Lk	R2/myu	0,033796 m	Guide vane length
v_3	(Lk*m*v2*sin(alfa1)*cos(alfa2 - betta))/(2*R2) + v2*cos(alfa2 - alfa1)	7,1162 m/s	Velocity of water at nozzle inlet
L	Q/((1 - p/100)*Rs*v3*2*3,14/m)	0,13139 m	Vertical height of nozzle
S_3	2*3.14*Rs*(1 - p/100)*L/m	0,028105 m²	Nozzle inlet area
S_4	S3/2,5	0,011242 m²	Nozzle outlet area
eps_k	0.125*lamb*(1 - (S4/S3)^2)	0,00525	Energy loss coefficient in nozzle
sig	(d*(d - 1) + 1 - (eps_k + 1.25)/2)^0.5	2.0304	Intermediate calculation coefficient
v_4	v3*sig	14,449 m/s	Velocity of water at nozzle outlet
c	S3*v3^2*(sin(betta + sig))/(3.14*v4)	0,023557 m³/s	Defined coefficient
Rshould d	1.7*Rs	0,25736 m	Arm of force

The energy parameters of the hydroturbine were analyzed using mathematical modeling. CFD simulations were carried out in COMSOL Multiphysics 6.1 (CFD module), applying the standard RANS method and the "Turbulent Flow, k-ε" model for five different guide vane and cone geometries. The velocity and pressure variations of water at different points of the nozzle were studied through mathematical modeling depending on nozzle geometry and number. This model achieves high accuracy in calculating Reynolds shear stresses and tensors for low-head flow gradients.

The dimensions and parameters of the small experimental hydroturbine used for simulation and laboratory testing are presented in Table 1.

3 RESULTS AND DISCUSSIONS

Figures 3 and 4 illustrate the changes in velocity and pressure fields of the hydraulic reaction turbine for both the conventional (non-improved prototype) and the improved internal guiding structures.

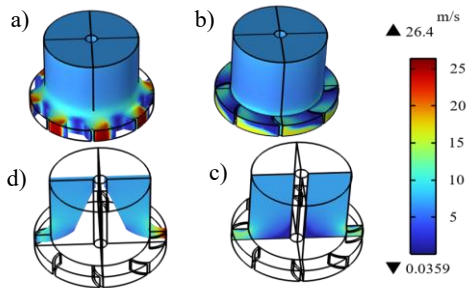

Figure 3: Analysis of water flow velocity field in hydroturbine guide devices: (a) 3D view of water flow in the improved guiding device; (b) 3D view of water flow in the conventional device; (c) water flow characteristics in the XOZ plane of the improved guiding device; (d) water flow characteristics in the XOZ plane of the conventional guing iddevice.

As can be seen from Figure 3, in the conventional turbine (right), multiple red and yellow zones (~20–26) are present around the device. These zones indicate strong turbulence, vortices, or regions of flow acceleration and deceleration. Particularly between the lower vanes, strong flow irregularities and energy losses are observed. In the improved turbine (left), the color gradient is smoother, dominated by blue and green areas (~5–15), which reflects a more stable flow - laminar or optimally turbulent. The flow is more centralized with fewer vortices and reduced turbulence.

Focusing on the inter-vane flow, in the conventional turbine, high-velocity regions in the lower section change abruptly, producing swirling motions inside the flow that generate additional resistance and reduce efficiency. In contrast, in the improved turbine, the inter-vane flow is more centralized and smoother. This condition indicates reduced energy losses and better conversion of flow energy into mechanical energy, attributed to minimized heat losses and vortex formation in the improved design.

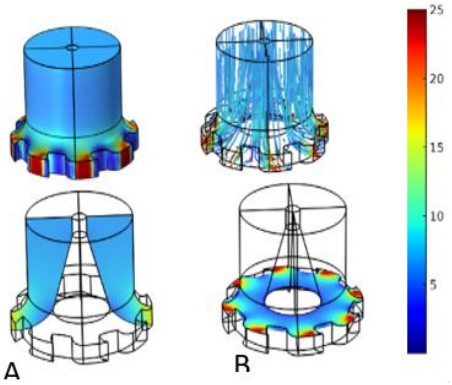

Figure 4: Fluid interaction in the improved internal guiding device of the hydroturbine: (A) velocity distribution; (B) pressure distribution.

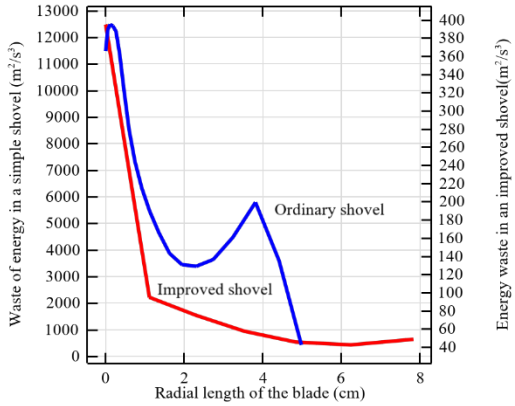

Figure 5: Energy losses due to turbulence in conventional and improved guiding devices with vanes.

From the pressure distribution analysis shown in Figure 4, it is evident that in the conventional guiding device, the water jet exiting the window expands and produces a vortex-like motion, leading to significant energy dissipation due to eddies and sudden expansion. This reduces the torque applied to the runner. In contrast, in the improved guiding device, the water flow passes through the guiding window without changing the spacing between the vanes,

directed toward the nozzle walls, producing maximum torque on the runner. The properly aligned and accelerated jet towards the nozzle walls increases turbine efficiency.

As illustrated in Figure 5, comparison of the flow zones between conventional and improved vane-type hydroturbines reveals the following observations:

- In the initial zone (0 – 1.5 cm), the turbulence dissipation rate is very high (~5000+ m^2/s^3) for the conventional vane design (blue), whereas in the improved vane design (red/green), turbulence and energy dissipation are significantly lower. The smoother acceleration of the flow in the improved vane reduces energy losses.
- In the middle zone (1.5 – 6 cm), turbulence sharply decreases (from 5000 → ~1000 m^2/s^3), indicating rapid attenuation of instability in the flow. The improved vane maintains flow stability over a longer distance, which enhances aerodynamic efficiency and reduces system friction.
- In the final zone (6 – 13 cm), the velocity in the conventional vane device drops considerably (~9 m/s), while in the improved vane device, velocity remains higher (~10–11 m/s). This demonstrates that energy is dissipated more slowly.

Thus, in the improved vane design, the flow remains more stable and energy-rich, ensuring improved heat transfer and higher driving power. Due to reduced turbulence and sustained high velocity, cavitation decreases, and the service life of the turbine is nearly doubled.

A small-scale model of the hydroturbine was fabricated and tested experimentally. The experimental results were compared with those of the conventional prototype.

It was found that there are almost no dedicated stands available for testing small-scale hydroturbine models; existing stands are large in size, equipped with outdated components, and suitable for testing only one or two turbine types with limited capability to vary water head and flow rate. Moreover, constructing a new turbine prototype for such stands requires significant financial costs.

Therefore, a test stand was developed that allows experimental studies of various pico-hydroturbine prototypes, along with a testing methodology (Fig. 6).

The fabricated stand has the following structure: a frame with two reaction hydroturbines installed, supplied with water through three low-pressure pumps (1.5 kW each). The inlet water pressure of the hydroturbine is monitored using four manometers. The rotary motion from the turbine shaft is transmitted via a pulley to a generator, with a transmission ratio of 2.2. The generated electricity is supplied to a specially designed transformer. The transformer output, including current and voltage, is measured and displayed on a control panel. As a load, two 50 W lamps and a 150 W resistance coil were used. The generated current and voltage were measured using Class A ammeters and voltmeters.

Figure 6: Experimental setup of the improved micro-hydroturbine model.

The water flow rate and pressure were regulated by controlling the rotational speed of the pumps using a frequency regulator, with the range varying from 0 to 5000 rpm. Additionally, water circulation before the pump was provided through valves to extend the range of flow and pressure control.

The small-scale nozzle-type reaction hydroturbine model was tested on this stand. During the experiments, water pressure at different points in the turbine was measured using manometers, the water flow rate was determined from a calibrated scale in the measuring tank, and the runner's rotational speed was measured using a tachometer.

The analytical, numerical, and experimental investigations conducted in this study demonstrate that the proposed internal guiding device - consisting of a diffuser cone and optimized guide vane geometry - significantly improves the performance of nozzle-type reaction turbines under low-head conditions.

Compared with the conventional design, the efficiency of the improved turbine reached 85.5%, which is 3.4% higher than that of the conventional turbine (82.1%). This increase in efficiency primarily results from two mechanisms: (i) the conical diffuser stabilizes the inlet flow to the guide vanes, reducing turbulence and secondary vortices; and (ii) the optimized guide vane geometry minimizes hydraulic losses and enhances energy transfer to the shaft.

In addition, the maximum rotational speed increased by almost 14%, confirming the enhancement of energy efficiency.

A comparison of analytical, CFD, and experimental results further supports these findings. Analytical evaluation showed an efficiency of 86.2%, CFD simulations yielded 86.6%, and experimental measurements recorded 85.5%. The close agreement between these values demonstrates the reliability of the proposed design and the validity of the adopted methodology. A deviation of less than 1.5% confirms that CFD, when supported by analytical theory and validated through experiments, can serve as an effective predictive tool for turbine optimization.

From a practical standpoint, the improved turbine is particularly well suited for rural electrification and irrigation canal systems, which are widely implemented in Uzbekistan and other developing countries. By reducing the risk of cavitation and extending the service life of the turbine by approximately 50–55%, the design not only enhances efficiency but also decreases maintenance costs and downtime, thereby improving overall economic feasibility.

4 CONCLUSIONS

This study focused on the improvement of the internal guiding device of a nozzle-type reaction turbine under low-head conditions through CFD modeling and experimental testing. The novelty of the work lies in the use of a conical diffuser and optimized guide vane geometry to control flow, reduce hydraulic energy losses, and enhance both efficiency and turbine service life.

The research employed analytical evaluation of flow, velocity, torque, and efficiency; CFD simulations using the RANS approach with the k–ε turbulence model in the COMSOL Multiphysics platform; and experimental testing of a 500 W prototype on a specially designed laboratory stand with an adjustable water head of 1.5–6 meters.

The results provided new scientific insights into the influence of internal guiding devices on turbine performance. The improved design reduced hydraulic losses by 35–40%, increased efficiency from 82.1% to 85.5%, and extended turbine service life by approximately 50–55%.

ACKNOWLEDGMENTS

The author would like to express sincere gratitude to Prof. Dr. R. Aliyev of Andijan State University for his valuable guidance, constructive suggestions, and support throughout the research process.

Keywords: Modelling, Supercapacitors, The Maximum Power Point Tracking MPPT, Bidirectional DC-DC Converters (BDC) Buck/Boost, PI Controller, Energy Density, Power Density.

Abstract: This paper presents the design and modeling of a hybrid energy storage system (HESS) for a grid-connected photovoltaic (PV) application. The proposed system integrates batteries and supercapacitors to address the inherent variability of solar power generation and to enhance grid stability. A boost converter is employed to regulate and elevate the PV output voltage, while a maximum power point tracking (MPPT) algorithm based on the incremental conductance method ensures optimal energy extraction under varying environmental conditions. The system is interfaced with the grid through a three-phase voltage source inverter controlled by pulse width modulation (PWM). The hybrid storage configuration combines the high energy density of batteries with the high power density of supercapacitors, enabling efficient management of both low-frequency and transient power fluctuations. A bidirectional DC–DC buck–boost converter with PI-based control is used to coordinate charging and discharging processes. Simulation results demonstrate that the proposed system effectively reduces power fluctuations, minimizes grid dependency during peak demand, and improves overall system reliability. Furthermore, the hybrid approach alleviates battery stress, thereby extending its operational lifetime. The study confirms that integrating hybrid energy storage significantly enhances the performance and stability of grid-connected PV systems.

1 INTRODUCTION

The power generation from renewable energy sources is inherently variable due to their dependence on fluctuating weather conditions. For instance, the energy output from recently deployed photovoltaic systems is highly variable [1], [2]. These energy fluctuations pose challenges to the stability of the public grid and the overall power system. Therefore, the use of energy storage systems can mitigate these instability issues. Since the inception of electrical energy generation, various effective technologies have been developed to store and utilize energy when demand arises. The energy storage industry has continued to evolve and advance technically, diversifying both the technologies and the methods for controlling power sources. This diversification aims to create a flexible energy infrastructure and achieve cost savings for both network owners and consumers. Batteries have been utilized as a crucial storage element, with research identifying the optimal size to minimize total operating costs [1]. Additionally, other energy storage systems, such as supercapacitors, have been employed to address the variability in the output power of distributed photovoltaic systems injected into the grid, demonstrating their impact on the safety and reliability of distribution networks [2]. Figure 1 illustrates the energy density and power density of each storage type, thereby determining the optimal operating range for each.

The concept of power density, which represents the maximum power that can be extracted per unit mass (W/kg), and the concept of energy density, which denotes the energy that can be expended from the source per unit mass (Wh/kg), are pivotal in the realm of energy storage. These concepts determine the optimal energy source based on the application. For instance, for long-term operation, sources with high energy density, such as certain storage

technologies with high energy density, are preferred to extend the operating time of the load. Conversely, when a large capacity is required irrespective of time, supercapacitors with high power density (KW/kg) are more suitable, making them ideal for applications like engine starting or braking [3], [13]. Consequently, it has been found that the advantages of both storage elements can be harnessed through a hybrid storage system. This system comprises as Figure 2.

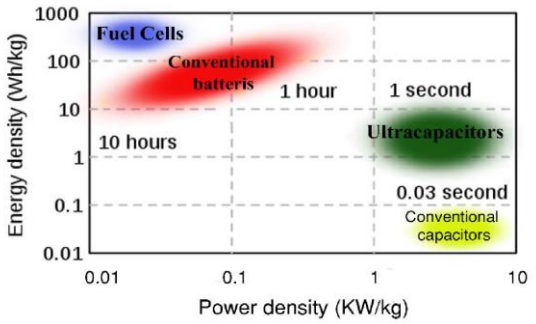

Figure 1: Energy density and power density of supercapacitors and Batteries [3], [13].

Energy Storage unit (ESU1): Designed to meet high power demand and rapid, transient load changes, characterized by fast response time, high efficiency, and long-life cycle.

Energy Storage unit (ESU2): Intended for high energy storage, characterized by a low self-discharge rate and low energy installation cost [4], [14], [28].

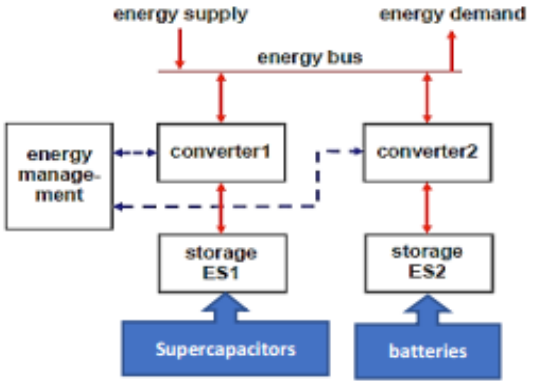

Figure 2: Basic structure of hybrid storage system.

The two storage units are charged and discharged using a bidirectional DC/DC converter. Borkowski ,D. Oramus ,P & Brzezinka ,M In [1], a dedicated control strategy for PV-BESS that maximizes the daily market DM revenue is proposed. The algorithm for determining the control strategy was implemented using analytical methods based on complete data on PV production and energy prices. Furthermore, the control strategy was implemented in a sizing algorithm that optimized the financial criteria. The effectiveness of the algorithm was demonstrated through an example of real 1 MW PV data. A 10-year analysis of the system operation using the additional control mode indicated a significant increase in the rate of return of the energy storage, reaching 15 % for the high PV penetration price profile. Gonçalves, A. Cavalcanti, G & Feitosa, M&..etc In [2] the size of the BESS system was determined to supply energy to the load of auxiliary systems of an ESS, as well as a PV system to achieve a null total cost. Furthermore, multi-objective optimization using the genetic algorithm technique was employed to optimize the size of the hybrid PV/BESS to minimize the investment cost and time when the demand was not met. Simulations under different scenarios of contingency were allowed to obtain the Pareto frontier for the optimal sizing of a PV/BESS system to supply energy to AC auxiliary systems in an ESS under contingency. Member, S., & Ongaro, F [3].at the University of Udine, Italy, this study focused on extending the lifespan of batteries powering wireless sensors. A DC-DC converter was used to control input voltage and increase power, while a statistical method based on recorded energy data determined the energy storage elements' size. Results showed a significant reduction in charge/discharge cycles of Li-ion batteries, improving their lifespan and confirming the design procedure's validity. Karshenas, Kurtoğlu1, M,&Eroğl, F. In [4] a non-isolated BDC, has a buck and boost principle of operation, is designed, analysed and simulated under various case studies. In the designed system, BDC controls the bidirectional power flow between the battery and DC link. Specifically, in the charging stage of battery operating in buck mode, DC-link supplies the power to the battery and BDC regulates the battery current using proportional-integral (PI) controller. On the other hand, in the discharging stage of the battery operating in boost mode, when DC source is disconnected, the battery supplies the power to DC load and DC-link voltage is controlled by the BDC via PI controller. The simulation results are presented to show the operation and control of the BDC under different scenarios. Manuel, V., & Guerrero, M.Á [5] This research presented a 30 KW photovoltaic system connected to the grid, aiming to develop a method for calculating energy storage system size using energy curves and fuzzy control methods. As for Rajasekaran, R., & Rani, P.U [6] this study employed an energy management algorithm for a standalone

(PV + wind) system to achieve microgrid self-sufficiency. In [7] discusses the transition to renewable energy systems and the challenges of energy storage within them. It addresses the issues of optimizing the capacity of hybrid energy storage systems and their environmental impact. The study presents new strategies to enhance the utilization of these systems and reduce greenhouse gas emissions. Saritha.K.& Sharma.S & another [8] discusses green energy storage technologies, which are a key element in reducing carbon emissions and integrating renewable energy sources. It examines the use of Energy Storage Systems (ESS) to store surplus electricity and make it available on demand to reduce fluctuations. The study reviews green energy storage systems and presents new strategies to enhance their utilization and reduce greenhouse gas emissions.

The current work aims to design and model a hybrid storage system of batteries and supercapacitors for a photovoltaic system that can be connected to the grid. This system can connect regardless of source voltage changes and works to elevate and regulate the output voltage of the photovoltaic system using a boost converter, to operate at the maximum power point of the cells' output. The output voltage then feeds a three-phase voltage inverter driven by PWM (Pulse Width Modulation) technology. When the output power of the photovoltaic system decreases, the stored energy in the batteries and supercapacitors can be utilized, as illustrated in Figure 3.

Based on this study, a hybrid storage system comprising batteries and supercapacitors, along with the necessary bidirectional DC/DC converter (buck-boost) for charging and discharging, was adopted in this research.

2 SYSTEM CONSTRUCTION

The subsequent sections will outline the design equations necessary for a grid-connected photovoltaic system is depicted in Figure 4 (PV system, Boost Converter, Three-phase inverter, Passive filters and grid). as well as the equations required for designing the hybrid storage system and its control components. Additionally, the computer model used to evaluate the overall system performance will be presented.

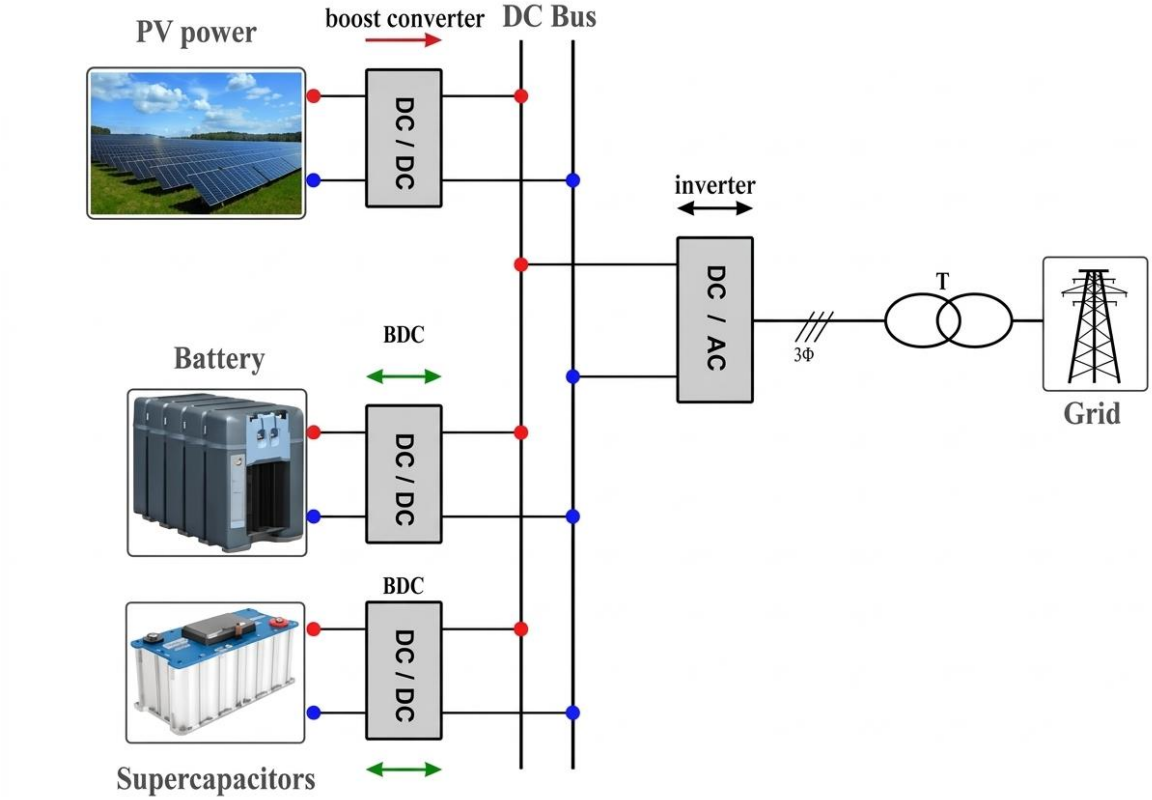

Figure 3: Basic components of the system [9].

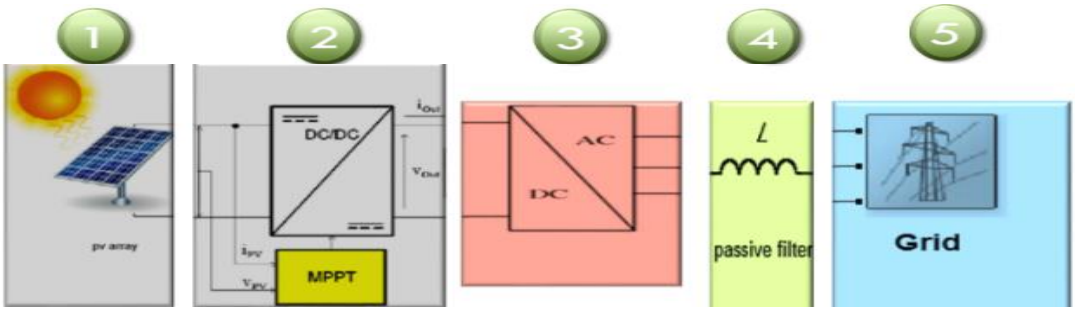

Figure 4: Steps for designing and modeling a grid-connected photovoltaic system.

2.1 PV System

The photovoltaic system array consists of multiple strings connected in parallel, where the total number of modules is calculated using the following relationship:

$$N_{modul} = \frac{P}{P_m}. \quad (1)$$

- P: PV system power [W], P_m: PV module power [W].

The number of modules in a string is calculated as follow

$$N_{m,string} = \frac{V}{V_m}. \quad (2)$$

- V: PV system voltage [V], V_m: PV module voltage [V]

The number of strings connected in parallel is given by:

$$S_p = \frac{N_modul}{N_(m,string)}. \quad (3)$$

To design a photovoltaic array with a capacity of 10 [kW] and maximum output voltage of 200 [V] and select a module with a capacity of 630 [W] and maximum output voltage of 46.02[V], the components of the array are determined based on the relationships above (1), (2) and (3):

$$N_{modul} = 16\ ,\ N_{m,string} = 4\ ,\ S_p = 4.$$

2.2 Boost Converter

The boost converter functions to elevate the output voltage of the PV array, as illustrated in Figure 5.

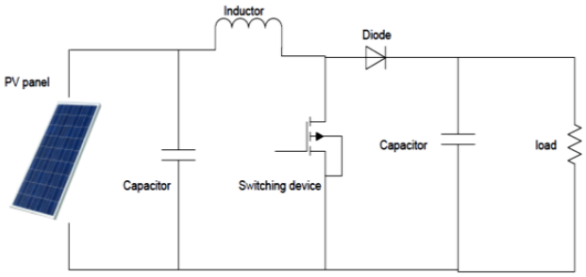

Figure 5: Components of the Boost Converter [10].

The duty factor D, inductor L and capacitor C of converter is calculated according to [15]:

$$D = 1 - \frac{V_i}{V_o},\ L = \frac{(1-D)^2 \times D \times R}{2F},\ C = \frac{D \times V_o}{R \times F \times \Delta V_O}. \quad (4)$$

- V_I: converter input voltage [V];
- V_o: converter output voltage [V];
- R: output resistance [Ω];
- F: chopping frequency [HZ];
- ΔV_O: output voltage ripple [%].

In order to design a boost converter, its input voltage is equal to the output voltage photovoltaic array, 200[V], and its output voltage is 400[V] with ΔV_O<1%, R =500 [Ω], F =50000[HZ] assumed.

Using (4) the nominal values of the elements are determined:

D= 0.5, L= 625*10-6 [H], C = 888*10-6 [F]

2.3 Maximum Power Point Tracking (MPPT)

The incremental conductance method has been selected due to its effectiveness in handling significant variations in weather conditions [16]. This method depends on the values of the slope of the (P-V) curve as in Figure 6.

At the maximum power point:

$$\frac{dI_{PV}}{dV_{PV}} = -\frac{I_{PV}}{V_{PV}}.$$

To the left of the maximum power point:

$$\frac{dI_{PV}}{dV_{PV}} > -\frac{I_{PV}}{V_{PV}}.$$

To the right of the maximum power point:

$$\frac{dI_{PV}}{dV_{PV}} < -\frac{I_{PV}}{V_{PV}}.$$

Therefore, the flow chart for this method is as shown in Figure 7. Figure 8 shows modeling of this method in Matlab.

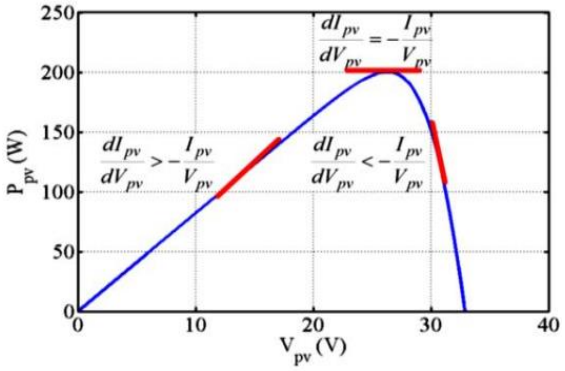

Figure 6: Illustrates the method of increasing conductivity by inclining (power-voltage) curve [10], [16].

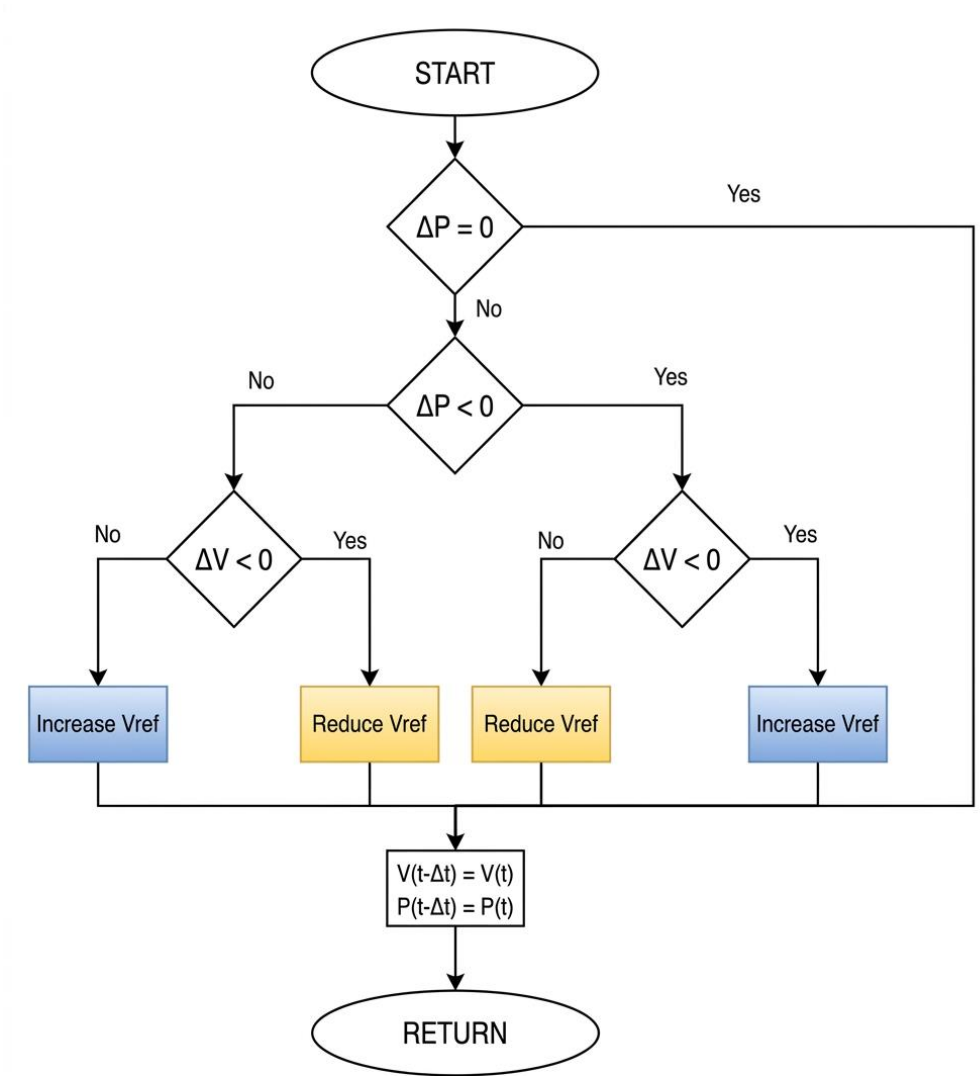

Figure 7: Flow chart of the conductivity increase method [10].

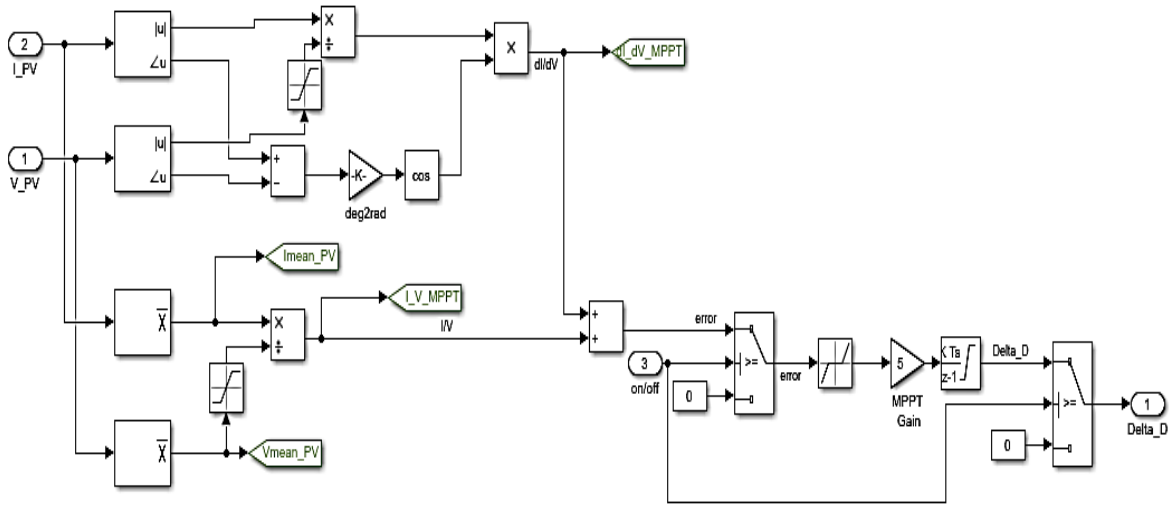

Figure 8: Modeling the conductivity increase method in Matlab.

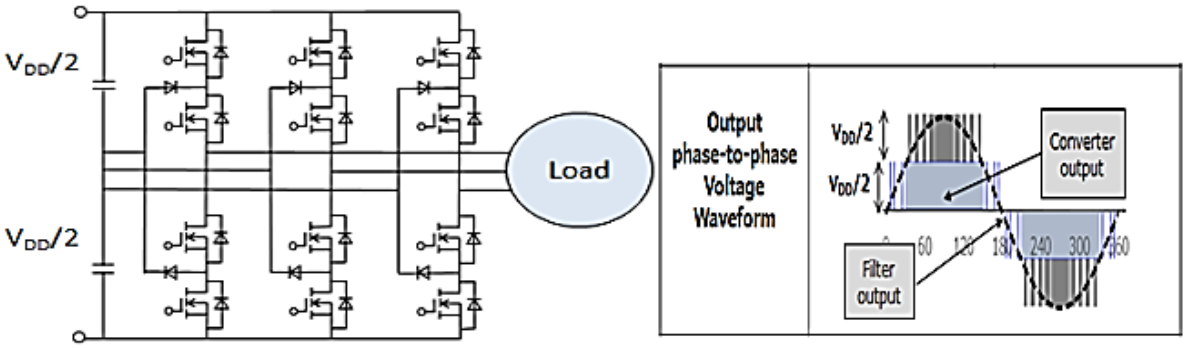

Figure 9: Three-phase inverter structure.

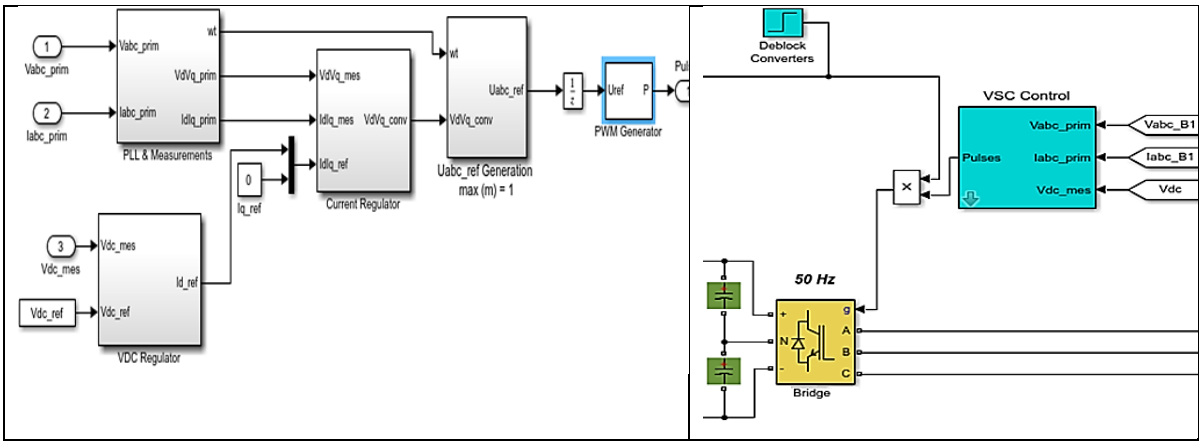

Figure 10: Modeling of a three-phase inverter driven by PWM technology.

2.4 Three-Phase Inverter

The DC input voltage of the inverter must be:

$$VDC > [\sqrt{2}\ V_g\ ]. \quad (5)$$

V_g: grid voltage.

$$VDC > (\sqrt{2} \times 220) > 311 = 400\ [V]$$

The three-phase three-level bridge as shown in Figure 9 is a bridge consisting of three arms, each arm having four IGBT elements, two upper and two lowers [17]:

The three-phase inverter-driven PWM is modeled as shown in Figure 10.

2.5 Passive Filters

A three-phase transmission line, which functions as an inductor, is utilized to transfer the maximum power from the photovoltaic panels to the public grid [18]. The inductance is calculated using following:

$$L = \frac{E^2}{2\pi F \times P_{max}}. \quad (6)$$

E: line voltage of grid [KV]. P max: maximum power transmitted by three phases [MW]. F: grid frequency [HZ].

Considering: P_{max} =10[KW] = 0.01[MW]، F =50[HZ]، E= 380[V] =0.38[KV].

The value of inductance for each phase is:

$$L = 0.38^2 / (2\pi \times 50 \times 0.01) = 0.046[H] = 46[mH]$$

This inductor also acts as a passive filter for current, then photovoltaic system is connected to a transformer center that raises the voltage from 380[V] to 20[KV] and then to public grid 20[KV].

3 HYBRID ENERGY STORAGE SYSTEM (HESS)

The maximum energy required to be provided by the hybrid storage system must be known, as calculated from [5], [19]:

$$E_{max} = \frac{P_{PV,nom}}{3600 \times T_m}. \quad (7)$$

- $P_{PV,nom}$: Nominal power generated by the cells [KW];
- T_m: Power management time [S].

Assuming that: $P_{PV,nom}$= 10 [KW], Tm=30[min]×60=1800[S]

We find: E max="10[KW]" /3600×1800 [S]=5 [KWh].

The percentage distribution of energy between batteries (E_b) and supercapacitors (E_{sc}) is calculated based on the ratio between the time constant of the battery response (τ), which is inversely proportional to the battery stress, and the energy management time Tm, batteries and supercapacitors energy is given as follows [11]:

$$E_b = \frac{1-\tau}{T_m} \times E_{max}, E_{sc} = \frac{\tau}{T_m} \times E_{max}, \quad (8)$$

We will design a hybrid storage system (comprising batteries and supercapacitors) following these steps:

1) Determine the parameters of the batteries (number, type, and specifications).
2) Determine the parameters of the supercapacitors (number and specifications).
3) Design a Buck/Boost converter for charging and discharging the batteries and supercapacitors

3.1 Battery Parameters

Lithium-ion batteries were selected due to their numerous advantages over other types, including higher efficiency and energy density (90%, 125 [Wh/kg]), increased nominal voltage (3.7 [V] per cell), lower weight, longer lifespan, faster and more efficient charging, smaller size, no maintenance requirements, and greater resistance to external conditions [11], [20].

Therefore, we select a GTK Lithium-ion battery C-2440H, with the following specifications [21]:

U_b = 24 [V], Cb = 30 [Ah] : τ=2.4 [min]

And considering: T_m = 30[min], and by compensating for (8) is:

$$E_b = 4.6\ [KWh]$$

To determine the number of batteries needed, we follow these steps:

1) Determine the required voltage of the battery matrix:

$$U_{b-total} = 200\ [V].$$

2) Determine the amount of energy required from the batteries:

$$E_b = 4.6/0.7 \approx 6\ [KWh].$$

Note: Since lithium-ion batteries operate in the capacity range of 25-95%, for safe use, only 70% of the theoretical energy is available [10][22]. Therefore, the calculated value of the total energy that

the battery should provide should be divided by 0.7 to obtain the correct values.

3) Calculate the total capacity of the batteries:

$$C_b = \frac{E_b}{U_{b-total}} = 30\ [\text{Ah}]. \quad (9)$$

4) Calculate the number of batteries in series:

$$N_S = \frac{U_{b-total}}{U_b} = 200/24 \approx 8. \quad (10)$$

5) Calculate the number of parallel strings:

$$N_B = \frac{C_{b-total}}{C_b} = \frac{30}{30} = 1. \quad (11)$$

6) Calculate the total number of batteries:

$$N = N_s \times N_b = 8. \quad (12)$$

3.2 Supercapacitors Parameters

From (8) in the previous section, we determined that the energy required from supercapacitors is:

$$E_{sc} = \frac{\tau}{T_m} \times E_{max} = 0.4\ [\text{kWh}].$$

To determine the specifications and number of capacitors, we select a supercapacitor from Maxwell Company, model BMOD0165 P048 C01with the following specifications [23]: U_{sc}=48 [V], C_{sc}=165 [F].

To determine the number of supercapacitors required, we follow these steps:

1) Determine the required capacitor array voltage:

$$U_{sc-total} = 200\ [\text{V}]$$

2) Determine the amount of energy required from the supercapacitor:

$$E_{sc} = 0.4\ [\text{KW}h].$$

Note: The supercapacitor module is typically designed to operate between the nominal voltage of the module $U_{scmax} = U_{scn}$ and half of its nominal voltage $U_{scmin} = \frac{U_{scn}}{2}$, Hence [2], [24]:

$$E_{sc} = \frac{3}{4}\left(\frac{1}{2} \times C_{sc-total} \times U_{sc-total}^2\right). \quad (13)$$

3) Calculate the total capacitance of the supercapacitor:

$$C_{sc-total} = \frac{E_{sc}}{0.75 \times 0.5 \times U_{sc-total}^2} = \frac{0.4 \times 1000 \times 3600}{0.75 \times 0.5 \times 200^2} = 96[F]. \quad (14)$$

4) Calculate the number of supercapacitors in series:

$$N_s = \frac{U_{sc-total}}{U_{sc}} = \frac{200}{48} \approx 4. \quad (15)$$

5) Calculate the total capacitance of the series:

$$C_s = \frac{C_{sc}}{N_s} = \frac{165}{4} = 41[F]. \quad (16)$$

6) Calculate the number of parallel strings:

$$N_b = \frac{C_{sc-total}}{C_s} = \frac{96}{41} = 2. \quad (17)$$

7) Calculate the total number of supercapacitors:

$$N = N_s \times N_b = 8. \quad (18)$$

3.3 Buck/Boost Converter

Figure 11 shows the structure of buck/boost converter.

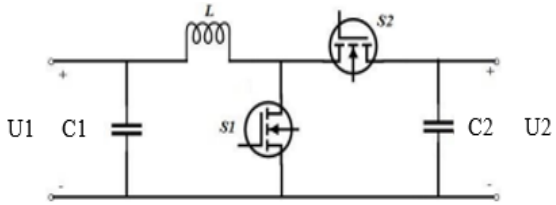

Figure 11: Buck/boost converter component [12].

The converter is designed taking into account the following requirements.

Output power (output power of the branch section at voltage 400 [V] where the output current of the array is 47.5 [A]) P_o =19000[w], Input voltage: U_1 = 200 [V], Output voltage: U_2 = 400 [V].

Chopping frequency F_s = 20000 [HZ], $\Delta U \leq 1$ [%]

Therefore, the maximum current of the IGBT is:

$$I_s = \frac{P_o}{U_1} = 95[A]. \quad (19)$$

If we consider the tolerance to be twice as large to get the maximum power from the storage source [12], [25], we find: $2 \times I_s$ = 190 [A].

The maximum voltage of IGBT is: IGBT V_{max} = U_2= 400 [V]. Considering the overload, the high voltage resulting from switching, and other factors, the maximum voltage of the IGBT should be greater than 400 [V].

As for the duty cycle factor, there are two factors:

The first is when the converter is in the boost position, which is:

$$D_1 = \frac{1-U_1}{U_2} = \frac{1-200}{400} = 0.5. \quad (20)$$

The second is when converter is working in buck mode, which is:

$$D_2 = \frac{U_1}{U_2} = \frac{200}{400} = 0.5. \quad (21)$$

The value of the inductor is calculated based on the following:

$$L = \frac{U_1 \times D_1}{\Delta I \times F_S}. \quad (22)$$

But according to engineering experience, half the current through the inductor is chosen to be 30% of the current Is. This enables us to obtain the minimum value of the inductor [26], [29], so it is:

$$\frac{\Delta I}{2} = 0.3\, I_s \;\rightarrow\; \Delta I = 0.6 \times I_s = 57. \quad (23)$$

By substitution in (22), L is:

$$L = \frac{200 \times 0.5}{57 \times 20000} = 88 \times 10^{-6}[H]. \quad (24)$$

For modeling L = 100 [mH].

As for the capacitance C_1, it is calculated in the reduced position according to:

$$C_1 = \frac{U_2 \times D_2 (1 - D_2)}{8 \times F_S^2 \times L \times \Delta U}. \quad (25)$$

Substituting the design requirements, we find:

$$C_1 = \frac{400 \times 0.5(1-0.5)}{8 \times 20000^2 \times 100 \times 10^6 \times 0.01} = 0.03 \text{ [F]}. \quad (26)$$

As for the capacity C2, it is calculated in boost position according to:

$$C_2 = \frac{I_O \times D_1}{F_S \times \Delta U}. \quad (27)$$

And it is:

$$I_o = \frac{P_o}{U_2} = \frac{19000}{400} = 47.5[A]. \quad (28)$$

$$C_2 = \frac{47.5 \times 0.5}{20000 \times 0.01} = 0.12[F]. \quad (29)$$

3.4 Control of Buck/Boost Converter and Energy Management

The control is implemented using a voltage and current double closed-loop as the primary controller, as illustrated in Figure 12.

The control system comprises an external voltage loop and an internal current loop. The external voltage loop is obtained by comparing V_b with V_{ref}, and the difference signal is sent to the PI controller. The resulting signal then enters the current loop, where it is compared with Ib, and the difference signal is sent to the PI controller and subsequently to the PWM system. This configuration ensures stable voltage on the U_2 side and current on the U1 side [5], [27], [30].

For system energy management, the flow chart shown in Figure 13 was adopted.

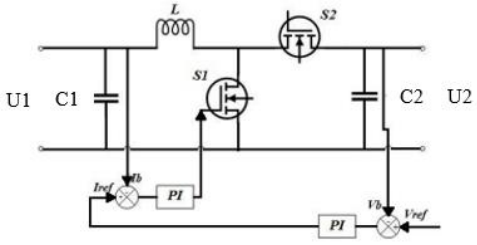

Figure 12: Control of bidirectional buck/boost converter [12].

4 MODELING OF THE PROPOSED SYSTEM AND RESULTS

Figure 14 shows modeling of the proposed system as a whole.

After operating the circuit shown in Figure 15, we obtained the following results:

4.1 Power

The energy stored in the batteries and capacitors will be utilized when the output power of the solar cells decreases. This occurs during the periods when the load obtains its energy from the grid, as shown in Figure 15, so power management time is: T_m=30[S]. Figure 16 shows us the (power-time) curve for each of the photovoltaic array power Ppv, the grid power Pg, the load power P_l, the batteries power P_{ba}, and the supercapacitor power P_{sc}.

We note that batteries acted as a high energy density storage element to meet the low frequency power requirements, and were discharged when the PV system output power decreased ($P_l > P_{pv}$) during the time periods (0-0.75), in order to cover the load requirements, when P_{pv} = 0 during the periods (0-0.57), the batteries discharged their energy to the load and the grid, and when the PV system started to produce power during the periods (0.57-0.75), the load was fed from the PV system and the batteries together (the batteries were discharged to the minimum charge state), and the excess power was injected into the grid, and at the minimum charge state at time 0.75, batteries stopped discharging and the load was fed from the PV system, after which it became ($P_l < P_{pv}$) during the time periods (0.75-1.7), and then the PV system started to charge batteries and feed the load in addition to injecting The excess power in the grid until the batteries were fully charged

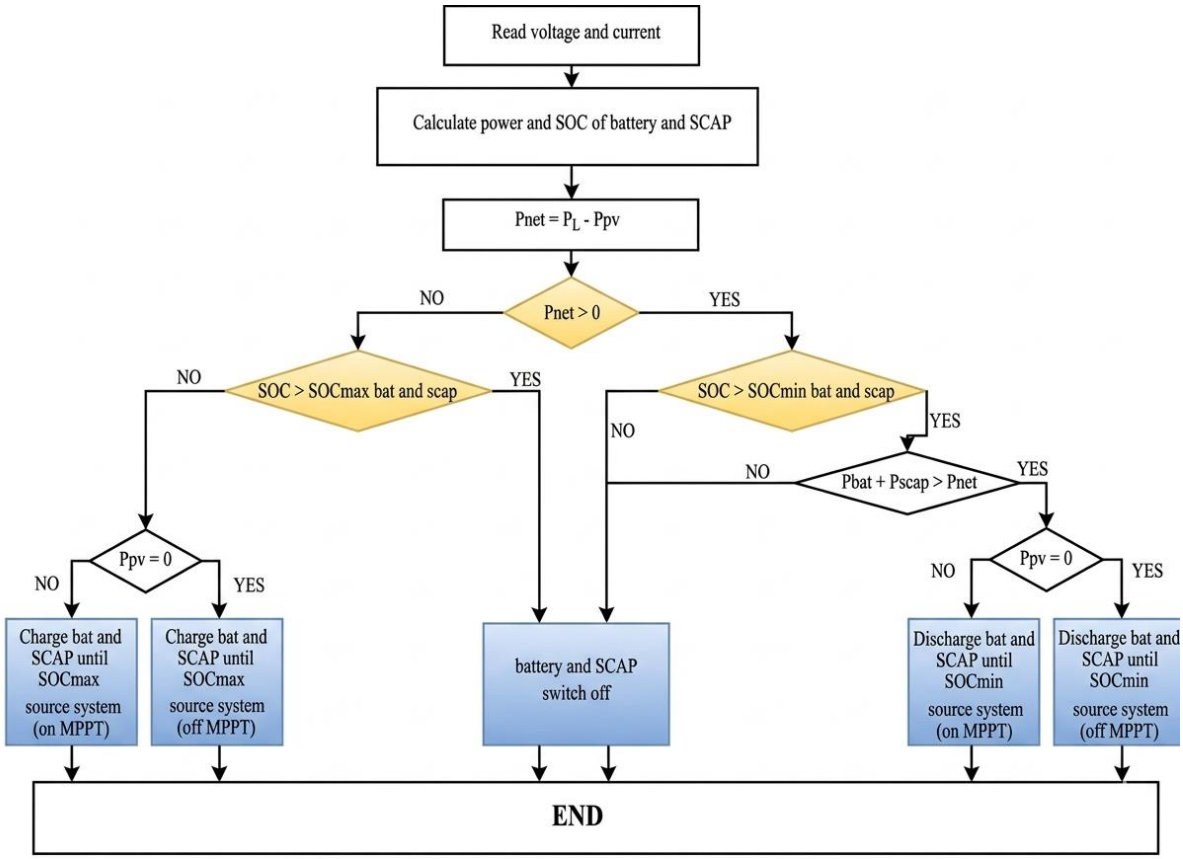

Figure 13: Flow chart for system energy management.

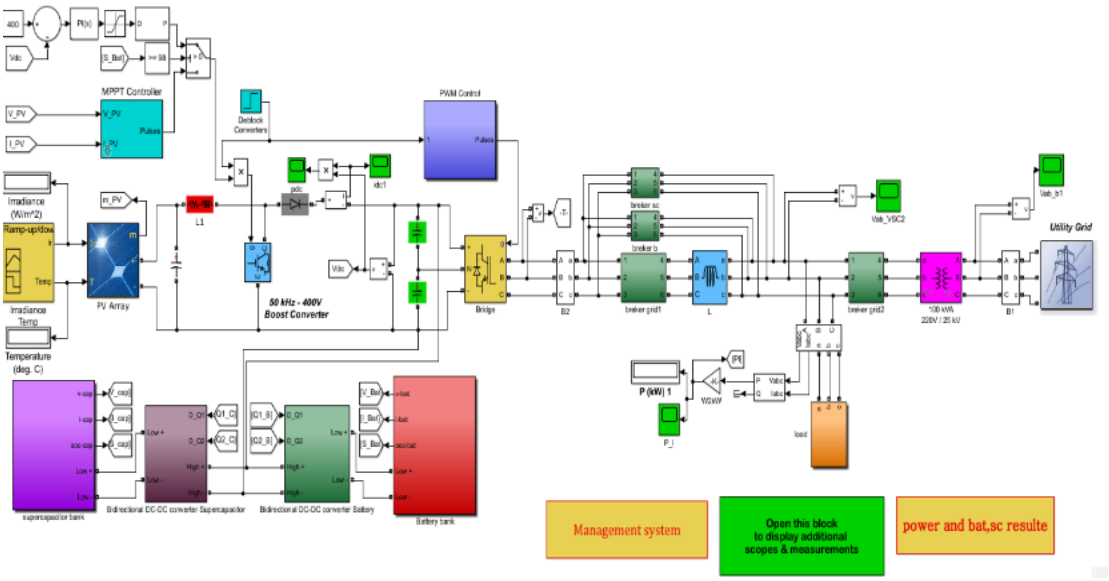

Figure 14: Modeling of the proposed system.

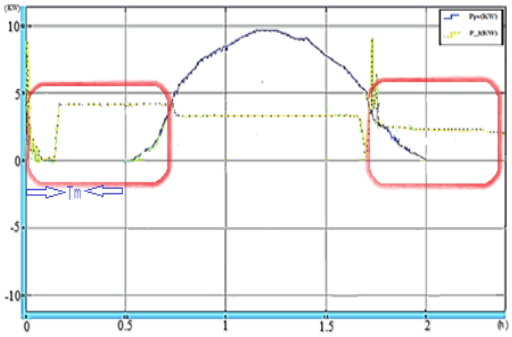

Figure 15: The periods during which the load obtains energy from the grid.

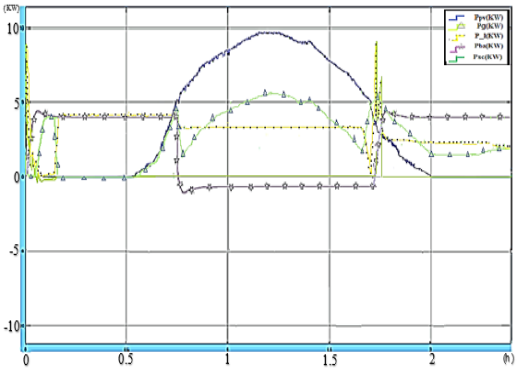

Figure 16: The power-time curve: P_{pv}, P_g, P_l, P_{ba}, P_{sc}.

(maximum charge state) at time 1.7, then the system continued to feed the load and the remaining power was injected into the grid, then a new battery discharge phase began. The supercapacitors acted as a high-energy density storage element to respond to high-frequency power requirements (transient load periods), as they were charged and discharged during these periods (0-0.04, 1.75-1.79).

As a result, when comparing Figure 16 and Figure 17, we notice that the batteries and supercapacitors work to cover the load requirements when the PV system power decreases, and thus reduce the draw from the grid (injecting excess power) while improving its stability.

4.2 Batteries Parameters

Figure 17 shows us the changes in the battery voltage v-bat, its current I-bat, its state of charge S-bat, and its capacity pbat concerning time:

From Figure 17, we observe that the batteries were discharged (the state of charge dropped from 80% to a minimum of 20%) when the photovoltaic system was unable to meet the load requirements. The output voltage of the batteries dropped to approximately 200 [V], the discharge current was about 23 [A], and the discharged power was 4.5 [kW]. Subsequently, the charging phase began (the state of charge rose from 20% to nearly 90%). The output voltage of the batteries was around 230 [V], the charging current was about 5 [A], and the charged power was 1.15 [kW].

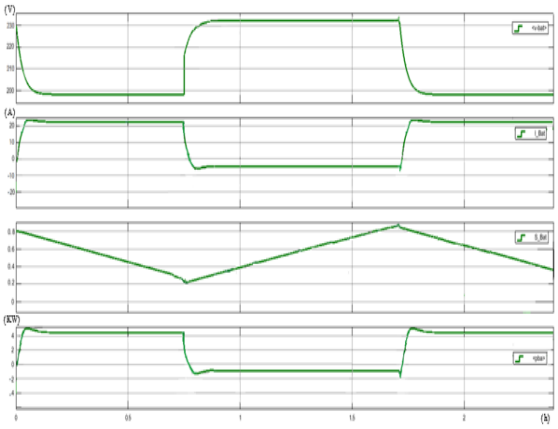

Figure 17: Changes in v-bat, I-bat, S-bat, pbat with Respect to Time.

4.3 Supercapacitors Parameters

Figure 18 illustrates the changes in the voltage of the capacitors V_{cap}, their current I_{cap}, their state of charge S_{cap}, and their capacity psc with respect to time:

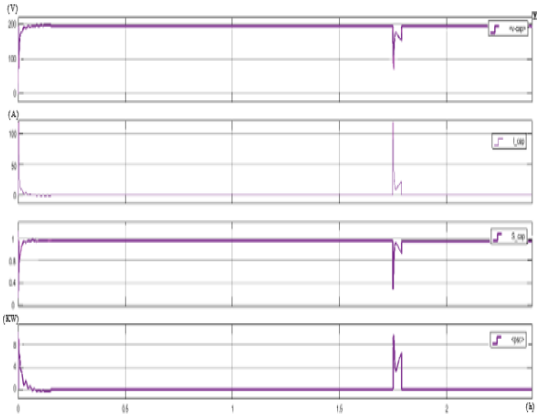

Figure 18: Variations of V_{cap}, I_{cap}, S_{cap}, P_{sc} with respect to time.

Figure 18 shows that the supercapacitors were charged and discharged with variable voltage and current to respond to high-frequency power requirements (transient load periods), thereby relieving the stress on the battery and stabilizing the public grid.

5 CONCLUSIONS

10 [kW] photovoltaic system was designed and modeled, demonstrating its ability to connect to the public grid regardless of changes in the input voltage of the panels, where the method of increasing conductivity were used to raise and regulate the output voltage of the cells to 400 [V] and to operate at the maximum power point.

The design and modeling of a three-phase voltage regulator driven by PWM technology resulted in an output voltage of 220 [V] for the alternating phase and 380 [V] for the line voltage, suitable for connection to the public grid.

A hybrid energy storage system consisting of batteries, supercapacitors, and a buck/boost converter was designed for charging and discharging, controlling their operation, and managing system power. The batteries acted as high-energy density storage elements to meet low-frequency power requirements, while the supercapacitors acted as high-power density storage elements to respond to high-frequency power requirements (transient periods). Both were discharged when the PV system output power decreased. Consequently, the power draw from the grid was reduced, and in some cases, the excess power was injected into the grid (which could be sold), thereby improving power quality and stability.

The energy required for both batteries and supercapacitors were calculated. It was found that considering a power management time of 30 minutes and a total stored energy of 5 [kWh], the ratio $\tau / T_m = 8[\%]$ is a good indicator that supercapacitors support the batteries for more than 2 minutes (30×8%=2.4), confirming that the supercapacitors have relieved the stress on the batteries, leading to an increased lifespan compared to an energy storage system that relies solely on batteries.

Keywords: Electric Power, Radiation, Reflector, Short-Circuit Current, Open-Circuit Voltage, PVTD, Temperature.

Abstract: An autonomous mobile photovoltaic–thermal device (PVTD) was developed to ensure reliable production of both electricity and hot water throughout the year, including during winter and summer seasons. The system creates the required solar radiation intensity even in harsh mountainous and foothill conditions, enabling stable performance under extreme climatic environments. In the experiment, two 200 W monocrystalline silicon photovoltaic (PV) panels and the PVTD were observed simultaneously, and the measurement results were compared through the calculation of power. The backside of the PVTD was equipped with a cooling system. It was also equipped with controllable reflectors that adjust according to seasonal changes in solar flux density. According to the experimental results, it was determined that the amount of energy produced by the PVTD was 1.81 times greater than that of the PV. In addition, by passing cold water at 9 °C through the collector located on the rear front side of the PVTD, usable hot water at 53 °C was obtained at a rate of 20 liters per hour. The experiment was conducted in winter months, under daily air temperatures ranging from –4°C to 5°C.

1 INTRODUCTION

PVs are widely used for energy production, however, most of their commercial versions currently have relatively low efficiency and convert only 13 to 20% of solar radiation into electrical energy under the ideal conditions specified in certification [1]-[3]. In the last few years, the demand for solar energy has risen dramatically due to high population growth, which has driven up the cost of non-renewable energy sources [4]. PVTD systems simultaneously produce electrical and thermal energy, which increases overall efficiency and reduces environmental impact [5]-[7]. Photovoltaic–thermal technologies (PVTD) have addressed the problem of overheating PV cells utilizing several cooling methods. These technologies can improve the electrical efficiency of PV cells and provide thermal energy simultaneously [8]. Advanced materials such as nanofluids are widely used by researchers around the world to increase the rate of heat transfer and to improve the efficiency of PVTD systems, including PVTDs [9]-[11]. Therefore, PV cooling methods are crucial to improving technology efficiency and prolonging its lifetime. Photovoltaic/thermal (PV/T) is a key to producing thermal and electrical energy, employing different fluids, including nanofluids (NFs) [12] The effect of reflectors on PVTD parameters has also been widely covered in many works, and their main function is to increase the radiation energy coming from the sun as well as to protect the PV from dust accumulation [13]. Thus, specialists, by choosing the widespread use of PVTDs in solar systems, are trying to determine ways to prevent heat loss between the PVTD and the environment. In this regard, they developed solutions against convection and radiation losses aimed at reducing heat loss [14]-[15]. Specialists have determined that the efficiency of PVTDs can be increased by adopting various approaches. Modern studies are aimed at developing advanced designs for solar collectors. Researchers strive to create solar collectors that describe minimal heat loss and maximum solar radiation collection, which

leads to high performance under average temperature conditions [16]-[17]. This study developed and experimentally evaluated an autonomous smart photovoltaic–thermal device (PVTD) designed for efficient year-round operation under highly variable climatic conditions, articularly in cold mountainous regions. The adaptive reflector system and integrated cooling module significantly enhanced both electrical and thermal output compared to a standard photovoltaic module.

2 METHODS AND MATERIALS

Due to the large number of cooling methods for PVTDs, this has aroused the interest of many scientists to conduct intensive research in this direction. It indicates the necessity of developing a specially constructed device with a solar tracking mode in mountainous and foothill regions. In particular, the fact that the energy produced by PVTDs in the winter months differs significantly compared to that in the summer months, as well as the difference in the rate of change of the temperature of the obtained hot water, causes a number of problems. In addition, in conditions of low air temperature, the possibility of obtaining hot water decreases. In order to eliminate these shortcomings, a device with a special construction was developed. The developed device creates the possibility of obtaining both electrical energy and hot water in the winter months, just as in the summer months. The developed PVTD has several advantages.

In particular:

- During the winter months, when ambient air temperature is low, additional reflectors allow for the collection of sufficient solar radiation flux density, thereby enabling the production of electricity and hot water comparable to that of summer conditions.
- The device is equipped with a special construction capable of solar tracking even in uneven terrains, due to its ability to move along two axes.
- Through the regulation of reflectors, it becomes possible to artificially generate a solar radiation flux density of around 1000 W/m² both in summer and winter, ensuring stable performance.
- To prevent the surface of the PV module from contamination, the reflective planes are used at night as protective covers against dust accumulation.

Table 1: Geometric dimensions of the components forming the PVTD.

Parameters		
1	Geometric dimensions	Size
2	Width of the PV frame, d	30mm
3	Surface area of the PV, S_{FEB}	0.9126m^2
4	Total surface area of the reflectors,, S	1.8252m^2
5	Thickness of the reflector, d_{ref}	0.4 cm
6	Thickness of the back cover, d_q	0.4 cm
7	Surface area of the back cover, Sq	0.9236m^2
8	Total weight of the PV, kg	8.55kg
Physical and technical characteristics		
1	Maximum power of the PV, P_{max}	200W
2	Efficiency of the PV, η	21.9 %
3	Open-circuit voltage of the PV, U_{OC}	21.6V
4	Short-circuit current of the PV, I_{SC}	12.22A
5	Fill factor of the PV, FF	0.76
6	Reflectance coefficient of the side reflectors R, m	0.5,1.17x78, 2 78x0.58, 1
7	Water capacity of the heat collector based on cellular polycarbonate, V m³	0.007316m^3
8	Battery, A·h	100Ah
9	Inverter, W	1000W

Figure 1: General view of the PVTD and reflector arrangement.

Figure 2: Structural layout of the PVTD thermal collector.

Figure 3: Electrical control and power conditioning subsystem.

In Figures 1, 2, and 3, the general view of the PVTD composed of a PV with a power of 200 W is presented. In order to reduce the energy losses caused by the increase in the surface temperature of the PV through cooling, and to obtain additional thermal energy, a photovoltaic-thermal device was developed. The developed PVTD is equipped with a cellular polycarbonate-based thermal collector and reflectors (Figures 1–2). In Figure 1, the structural parts of the PVTD for the reflector are shown, in particular, the PVTD consists of 4 reflectors. Of these, Reflectors 1 and 2 are installed on the two side surfaces of the PVTD, respectively. The geometric dimensions of the reflectors are equal, and the surface area of each is 0.9126 m² (Table 1). Reflectors 3 and 4 are installed at the top and bottom parts of the PVTD, and each has a geometric surface area of 0.4563 m². In general, the surface area of one reflector placed on the two side surfaces of the PVTD is equal to the total surface area of Reflectors 3 and 4 (Figure 1). The PVTD has a solar tracking mode, and a special construction capable of rotating 360° was developed. Furthermore, the PVTD was specially designed for uneven areas, including mountainous and foothill regions (Figures 1–2). The control system for the electrical energy generated by the PVTD consists of a battery (100 A/h) and an inverter (1 kW), and is systematized in a state protected from special external negative effects (Figure 3). The 4 reflectors that make up the PVTD serve to ensure that, across seasons, the changes in solar radiation flux density reach values in the range of 1000 W/m² to 1200 W/m². That is, in winter, 4 reflectors are used; in spring, two side reflectors and one top reflector; and in summer, two side reflectors are installed to achieve the required radiation. In particular, the distribution of the reflectors is carried out taking into account the percentage of daily sunshine duration and the values of daily solar radiation.

To ensure thermodynamic rigor and omparability with existing PV/T studies, the following governing equations are included.

$$Q_w = \dot{m} \cdot c_p \cdot (T_{out} - T_{in}) \quad (1)$$

where, $\dot{m}$-mass flow rate of water (kg/s), c_p-specific heat of water (~4180 J/kg·°C), T_{out}, T_{in}-outlet/inlet temperatures (°C).

Overall efficiency of the PVT panel is then found by.

$$\eta_{overall} = (P_{max} + Q_w)/(G_T \cdot A_C), \quad (2)$$

where, Q_w-is the thermal power gained by the working fluid, determined from the measured inlet and outlet water temperatures, mass flow rate, and the specific heat capacity of water. This value quantifies the amount of solar thermal energy converted into usable heat. P_{max}-is the instantaneous maximum electrical power generated by the PV module under the prevailing (non-standard) operating conditions. It is computed using the corrected values of short-circuit current I_{SC} and open-circuit voltage U_{OC}, along with the power ratio

R_p. Together, these two terms represent the combined thermal + electrical energy delivered by the hybrid panel. G_T-is the solar irradiance (W/m²) measured on the plane of the PVT panel. A_C-is the illuminated surface area of the PVT panel (m²). Thus, $G_T \cdot A_C$ represents the total solar power available to the system during operation.

At night, due to the higher dust accumulation compared to daytime, in order to prevent the efficiency of the PVTD from decreasing, the possibility of maintaining efficiency has been created by covering the front surface of the PVTD with reflectors at night (Figure 4). All four reflectors have also been made capable of being gathered and placed on the front surface of the PVTD.

.

Figure 4: Front surface view of the PVTD covered with reflectors.

3 RESULTS AND DISCUSSION

In this experiment, the aim was to create the possibility of obtaining in the winter months the same amount of energy as in the summer months by generating additional light intensity through reflectors in winter. The PV with a white protective coating used in the device has a power of 200 W. The experiment was carried out under real open-air conditions at the Institute of Physics and Technology, Helioplatform, after snowy precipitation, on 04.03.2025 from 09:40 to 15:00 in solar tracking mode in the horizontal direction. A special supporting construction was developed for the PVTD, designed for rotation around one axis and vertical movement fixed to a trailer. At the same time, the same conditions were created for the PV, and the experimental test results were obtained at 20-minute time intervals and the electrical parameters were measured. The experiment was carried out in solar tracking mode with the help of the special construction developed in the device (Fig. 5).

a) b)

Figure 5: a) Photothermal device b) Photovoltaic battery.

This experiment was conducted under an open sky on cold winter days after snowfall had ended. The purpose of the experiment was to determine, under real conditions, how much additional radiation could be directed to the PVTD compared to the PV, how much more power could be obtained, and how much hot water could be produced in cold winter weather conditions, as well as to confirm the feasibility of obtaining these outcomes.

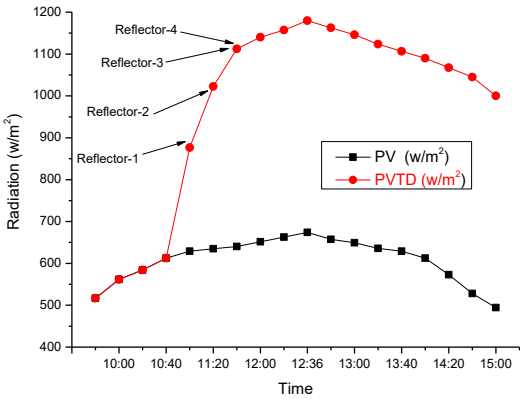

Figure 6: Dependence of perpendicular incident solar radiation intensity on the PVTD and PV surfaces over daytime hours.

In this graph, the solar radiation intensity was increased by means of special reflective mirrors, with each reflector being installed at specific time intervals and in a defined sequence, after which experimental results were obtained. In particular, it is clearly visible that the radiation intensities differ depending on the contribution of each reflector (Figure 6). At the initial stage, due to the reflectors, the intensity of light radiation on the frontal surface of the PVTD was increased up to 2 times (Figure 6).

The experiment began at 09:40, and by 10:40 the reflectors were installed at specific time intervals. When the 1st reflector was installed and measured at 11:00, the PV showed 560 W/m², while the PVTD showed 780 W/m², which is 220 W/m² higher. When the 2nd reflector was installed and measured at 11:20, the PV and PVTD registered 565 W/m² and 910 W/m², respectively. Together, the two side reflectors of the PVTD showed 345 W/m² more compared to the PV. Subsequently, when the 3rd and 4th reflectors were installed together and measured at 11:40, the PV registered 570 W/m², while the PVTD registered 990 W/m².

From the following measurements, as shown in this graph, it can be observed that the light intensity increased up to 2 times (Fig. 6).

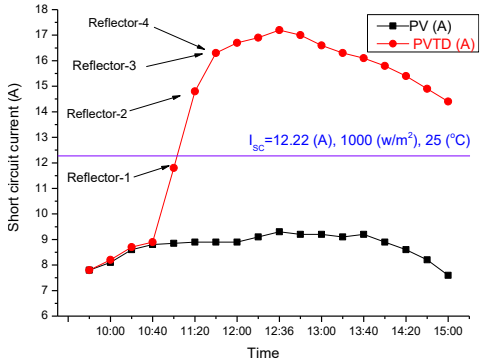

Figure 7:. Dependence of the short-circuit currents of the PVTD and PV on daytime.

The graph shown in Figure 7 illustrates the dependence of short-circuit currents on time. Considering the direct proportionality between light intensity and short-circuit current, the installation process of the reflecting mirrors, in particular the contribution of each reflector, makes it possible to clearly observe significant differences in short-circuit current. At 11:00, after the installation of the first reflector, the PVTD produced 11.8 A; at 11:20, after the second reflector was installed, it reached 14.8 A. At 11:40, when the third and fourth reflectors were installed simultaneously and measurements were taken, the PVTD showed 16.3 A (Fig. 7).

In the same period between 11:00 and 11:40, the PV short-circuit current increased from 8.5 A to 9 A. The reason for these PV values is that the solar radiation flux density during this time interval varied between 560 W/m² and 570 W/m², which correspondingly affected the short-circuit current.

In general, the short-circuit current of the PVTD was found to be 1.95 times higher compared to that of the PV.

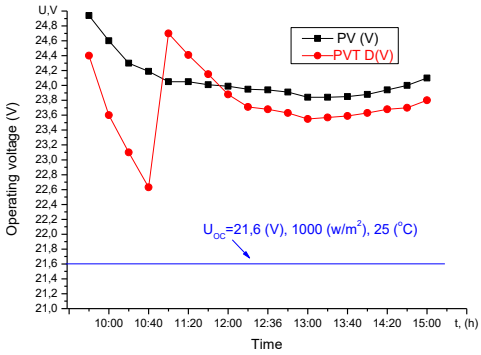

Figure 8: Dependence of the open-circuit voltages of PVTD and PV on daytime.

In this graph, the dependence of the open-circuit voltages of PVTD and PV on daytime is shown. It can be seen that the open-circuit voltage values of the PVTD compared to the PV are lower during the day. The reason for this is that the air temperature during the day was in the low range of -4 °C to 5 °C. Since the PV did not heat up sufficiently under the influence of low solar radiation flux density and air temperature, its open-circuit voltage did not decrease significantly.

In addition, in the PVTD, due to the accumulation of light flux density on the front surface through additional reflectors, it heated more. Initially, in the time interval from 10:00 to 10:40, it can be observed that the voltage drop of the PVTD compared to the PV decreased noticeably (Fig. 8). The reason for this is that a collector was located on the back frontal side of the PVTD, and since there was no convection inside the collector, the voltage decreased.

Between 09:00 and 10:40, the open-circuit voltage of the PVTD dropped from 24.4 V to 22.6 V. Afterwards, when 9 °C water was passed through the collector, the voltage temporarily increased to 24.8 V, and then it can be seen that the open-circuit voltage of the PVTD decreased again due to the additional solar radiation flux density accumulated

by the reflectors. Innovative designs of thermal collectors optimize heat dissipation from photovoltaic cells, which is crucial to preventing overheating and reducing efficiency losses [18].

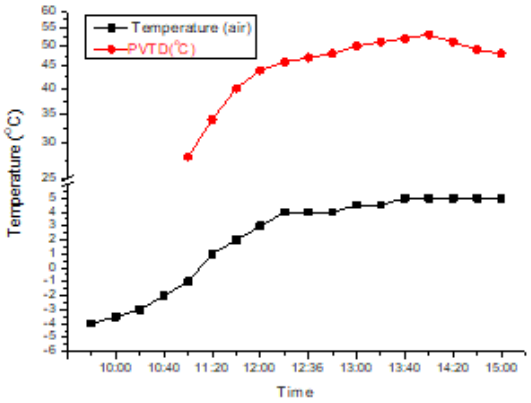

Figure 9: Dependence of air and hot water temperatures on daytime.

In Figure 9, the graphs of the dependence of air and hot water temperatures from the collector on daytime are presented. When water was passed through the collector and measured, the initial hot water results were taken starting from 11:00. The initial results showed 26 °C, and due to the increase of solar radiation flux density on the front surface of the PVTD by means of reflectors, it can be seen that the hot water temperature at the outlet of the PVTD cooling system increased up to 53 °C. Experimental research results were obtained at low air temperatures during the day, ranging from -4 °C to +5 °C. Based on the obtained results, power values were calculated and presented in the following graph.

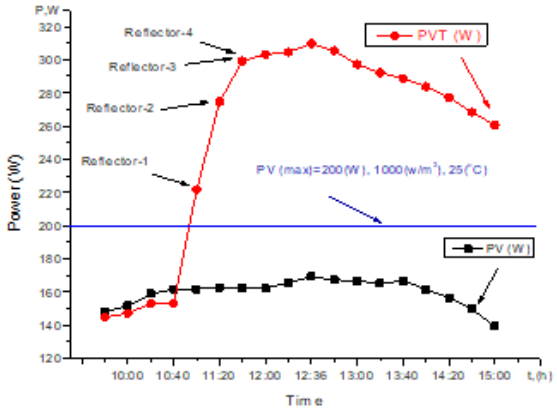

Figure 10: Dependence of PVTD and PV electrical power on daytime.

In the following graph, the overall differences in the electrical power of PV and PVTD are clearly shown. Until 10:40, since water was not passed through the cooling system of the PVTD, there was no open convection with air in the collector on the back side of the PVTD. As a result, the PVTD showed less power because it heated more compared to the PV. Then, at 10:40, due to the reflector and the cooling system, the open-circuit voltage and short-circuit currents improved. After the first reflector was installed, the power reached 221 W, which increased by 44% compared to the initial value. Under the effect of the second reflector, the power reached 274 W and increased by 20% compared to the initial result. When the 3rd and 4th reflectors were installed, the power reached 300 W, increasing by 9.5% compared to the initial value. In particular, the calculation results show that the average values of the electrical power generated by the PVTD during the day differ by 1.81 times compared to the PV (Fig. 10).

The findings of this study are consistent with previous research on PV/T systems and further strengthen existing conclusions. Earlier studies report that conventional PV panels typically convert only about 13–20% of incident solar radiation into electrical power [1]-[3]. In contrast, under the same conditions, the PVTD developed in this work generated 1.81 times more electrical power, mainly due to the combined effect of enhanced irradiance through reflectors and effective water-based cooling.

Previous literature highlights various cooling techniques - such as water cooling, nanofluids, and PCM - as key methods for improving PV/T efficiency [5]-[12]. In our system, four optical reflectors and active water cooling were employed simultaneously. As a result, the short-circuit current increased by 1.95 times, and the maximum output power reached 300 W, significantly exceeding the performance of the reference PV module.

Unlike many earlier studies conducted in warm or stable climates, our experiments were carried out in harsh winter conditions, with ambient temperatures ranging from –4°C to +5°C, using a two-axis solar tracking system. Despite the unfavorable environment, the PVTD maintained stable operation, delivering both sufficient electrical output and usable hot water. Additionally, the use of reflectors as night-time dust protection is a practical feature rarely discussed in the literature, further contributing to long-term efficiency.

In summary, compared with previous studies, the developed PVTD demonstrates the following advantages:

- higher efficiency through combined irradiance enhancement and cooling;
- reliable operation even in cold climate conditions;
- simplified cooling using ordinary water;
- dust protection through the reflector assembly.

4 CONCLUSIONS

Among renewable energy sources, the effective use of solar energy, which is considered the most promising direction, has become a priority area in the development of modern energy. For this purpose, the main electrical parameters of photovoltaic batteries (PV) and photovoltaic-thermal batteries (PVTD) were studied experimentally, and their comparison was carried out. During the research, the minimization of electrical losses in the device was set as the main goal. According to the obtained results, it was determined that the average electrical power produced by the PVTD is 81% higher than the average power produced by the PV. This situation demonstrates the multifunctionality of photovoltaic-thermal batteries and their high energy efficiency.

In addition, during the experiment, even when the air temperature was in the range of –4°C to +5°C, it was ensured that hot water with a temperature of 53 °C could be obtained at a rate of 20 l/h through the PVTD. This revealed that PVTD technologies are capable of producing not only electrical energy, but also thermal energy in a stable manner.

The overall efficiency of the photovoltaic–thermal device (PVTD) was evaluated based on its electrical and thermal energy outputs. The experimental results demonstrated that the device maintains high conversion efficiency even under real winter operating conditions. The thermal power of the system was determined from the temperature rise of the water flowing through the collector. With a water flow rate of 20 L/h and a temperature difference of 44°C between the inlet and outlet water (from 9°C to 53°C), the thermal power calculated using equation (1) was approximately 1020 W. The maximum electrical power generated by the PVTD reached 300 W, which is significantly higher than the power produced by the standard 200 W PV module used for comparison. For a thermodynamically accurate evaluation, the overall efficiency was calculated using the total optical aperture area of the PV panel and the reflectors. According to equation (2), the resulting overall efficiency was found to be approximately $\eta_{overall} \approx 48\%$. Moreover, this efficiency remained stable even under harsh winter conditions with ambient temperatures ranging from –4°C to +5°C. The experimental results validate the PVTD as a promising smart-energy solution combining solar electricity generation and thermal heating in a single autonomous platform. The device is well-suited for remote, high-altitude, and off-grid applications where conventional systems underperform due to fluctuating solar conditions.

Such high efficiency is attributed to the following factors:

- the increased solar irradiance intensity provided by the reflectors;
- the cooling collector reducing the temperature of the PV cells and thereby improving electrical efficiency;
- the high heat absorption capability of the thermal collector.

Keywords: Solar Radiation, ASHRAE Model, Hottel Model, Numerical Simulation, Experimental Comparison, Solar Insolation.

Abstract: This paper presents a comprehensive numerical modeling and validation of solar radiation intensity at the Earth's surface using three established clear-sky models: ASHRAE 2001, Hottel (1976), and ASHRAE 2009. The purpose is to evaluate their accuracy over the course of a year, based on simulation results computed using Python and MATLAB environments. Each model is applied to compute direct and diffuse solar radiation as a function of the day of the year and the tilt angle of the receiving surface. The computed values are graphically compared with experimental data to assess each model's relevance and limitations. Key performance metrics (mean bias error, root mean square error, etc.) are calculated to quantify model accuracy, and the results indicate that the ASHRAE 2001 model shows the closest agreement with measurements among the models tested. This study contributes to the optimization of solar energy system design and model selection for specific climatic conditions, and provides an open-source Python implementation for reproducibility.

1 INTRODUCTION

Solar radiation modeling is essential for designing renewable energy systems and analyzing climate-dependent parameters in buildings. Many empirical and semi-empirical models have been developed to predict the solar radiation reaching the Earth's surface. Among them, the ASHRAE 2001 and 2009 models, and the Hottel model (1976), are widely used in engineering applications. This paper analyzes and compares these models through numerical implementation and visualization, with a focus on their predictive capability throughout the year.

To place this work in context, accurate estimation of the direct and diffuse components of solar irradiance is a prerequisite for reliable sizing and performance assessment of photovoltaic arrays, solar thermal collectors, daylighting calculations, and building energy simulations. Model selection affects system yield estimates, economic feasibility studies, and the design of control strategies in building energy management. Although many models perform well under specific climatic regimes, their relative accuracy can vary substantially with atmospheric conditions (aerosol load, water vapor, cloudiness), site altitude, and the tilt orientation of the receiving surface. Therefore, comparative studies that evaluate model behavior against measured data are valuable for practitioners and researchers alike.

The main objectives of this study are: (1) to implement ASHRAE 2001, Hottel (1976), and ASHRAE 2009 models in Python (with cross-checks in MATLAB), (2) to compute hourly and daily direct and diffuse irradiance for a full year and for several tilt angles, (3) to compare model outputs with collocated experimental measurements, and (4) to quantify model errors and discuss their likely physical causes. In addition to numerical comparisons, we provide graphical diagnostics (time-series plots, scatter plots, and error histograms) to highlight where and when models deviate from observations.

This paper contributes in three practical ways. First, it provides a transparent, reproducible implementation of the three models in an open scientific computing environment (Python), facilitating reuse and further testing by other researchers. Second, it presents a systematic error analysis that separates systematic bias from random deviations and links error patterns to possible atmospheric causes (e.g., cloud-induced diffuse enhancement or aerosol-driven attenuation). Third, it offers design-oriented recommendations about model

choice and simple corrective strategies (such as empirical bias corrections or inclusion of a ground-reflected component) for applications in mid-latitude continental climates.

2 MODELING METHODOLOGY

Currently, there are many models available for assessing solar radiation reaching the Earth's surface. Numerous models have been analyzed in the scientific literature [1], [2], and their capabilities and accuracy levels have been studied. A common feature among these models is the use of the concept of the solar constant. This value represents the intensity of the solar radiation flux measured outside the Earth's atmosphere, perpendicular to the solar rays, and is typically taken as 1367 W/m² [3].

Due to the Earth's elliptical orbit around the Sun, the extraterrestrial radiation flux varies throughout the year: it reaches its maximum at the beginning of January (when the Earth is closest to the Sun), and its minimum at the beginning of July (when the Earth is farthest from the Sun). Several empirical formulas have been proposed to estimate the solar radiation at the Earth's atmospheric boundary, one of which is expressed as follows:

$$E_0 = E_{sc} \cdot \left(1 + 0.033 \cos\left(\frac{360n}{365}\right)\right) \quad (1)$$

where n represents the day of the year (e.g., January 1st, February 1st, etc.).

Moreover, one of the key parameters in radiation models is the relative air mass m. It represents the ratio of the actual path length that the solar rays travel through the atmosphere to the path length that the rays would travel through if the Sun were at the zenith. For example, at the zenith, $m = 1$, and when the zenith angle is 60°, $m = 2$. For angles between 0° and 90°, the m value can be approximated as follows [4]:

$$m = 1 / cos(\theta_z) \quad (2)$$

More refined empirical formulas are also available, which take into account the height h of the receiving surface above sea level.

Various models are used to assess solar radiation intensity at the Earth's surface. This study focuses on models that are independent of geographic location and are widely applied in many computational systems (including ANSYS Fluent): ASHRAE 2001, Hottel (1976), and ASHRAE 2009 [5]-[8].

2.1 Solar Geometry and Top-of-Atmosphere to Surface Reference

To convert the top-of-atmosphere irradiance (1) into useful surface quantities, standard solar geometry parameters are computed for each time step:

Solar declination (approximate):

$$\delta \approx 23.45^\circ \sin\left(\frac{360^\circ}{365}(284 + n)\right) \quad (3)$$

Solar zenith angle θ_z (via latitude ϕ, declination δ and hour angle ω):

$$cos\theta_z = sin\phi\, sin\delta + cos\phi\, cos\delta\, cos\omega \quad (4)$$

The extraterrestrial horizontal irradiance used as a reference is then

$$E_{\text{ex, horizon}} = E_{\text{ex}} cos\theta_z \ \ (for\ cos\theta_z > 0) \quad (5)$$

These quantities set the upper bound for surface irradiance and are the starting point for all atmospheric attenuation calculations.

2.2 Improved Air-Mass and Pressure Correction

For large zenith angles and non-sea-level sites, the simple relation (2) can be replaced with a standard empirical correction (Kasten & Young type) and a pressure correction:

$$\mathrm{m}_{K\&Y} = \frac{1}{cos\theta_z + 0.50572\,(96.07995^0 - \theta_z)^{-1.6364}} \quad (6)$$

$$\mathrm{m}' = m_{K\&Y} \cdot \frac{P}{P_0} \quad (7)$$

where P is local atmospheric pressure and P_0 is standard pressure ($1013.25\ hPa$). Using m' reduces bias in atmospheric extinction estimates at elevated sites.

2.3 Plane-of-Array (POA) Irradiance and Incidence Angle

When comparing model output to measurements on tilted surfaces (collectors), the beam, diffuse and ground-reflected components must be combined. The cosine of the angle of incidence θ between the sun ray and the collector normal is computed (common full expression shown compactly here; adopt sign convention consistent with your measurement azimuth):

$$cos\theta = sin\delta\ sin\phi\ cos\beta - sin\delta\ cos\phi\ sin\beta\ cos\gamma$$
$$+cos\delta cos\phi cos\omega cos\beta + cos\delta sin\phi cos\omega sin\beta cos\gamma$$
$$+cos\delta\ sin\omega\ sin\beta\ sin\gamma, \quad (8)$$

where β is tilt and γ is surface azimuth (convention: $\gamma = 0$ for surface facing equator).

POA irradiance is obtained by summing: beam on tilt (DNI·$cos\theta$), diffuse on tilt (isotropic or anisotropic partitioning), and ground-reflected component (albedo × global horizontal × geometric factor).

2.4 Practical Implementation Notes and Model Comparison Plan

The computational workflow for model evaluation was structured according to the following key steps:

- Use hourly time steps for model runs and aggregate to daily monthly totals for comparison with insolation records.
- Apply basic quality control to measurements (night removal, spike filtering, gap handling).
- Compute performance metrics (MBE, RMSE, MAE, R^2) and provide time-series and scatter diagnostics.

Detailed, model-by-model formulations and numerical implementation details for ASHRAE 2001, Hottel (1976), and ASHRAE 2009 will be presented in the next section(s). There we will implement and validate each model separately (equations, empirical coefficients, and any recommended corrections) and then run the head-to-head comparisons described above.

2.5 Implementation and Validation

The computational procedure for simulating solar irradiance was implemented in Python following a structured algorithm. The main steps of the algorithm are:

1) Initialize Constants: Set the solar constant I_0, site location (latitude, longitude, elevation), and define model-specific empirical coefficients (extinction coefficients, etc.).
2) Generate Time Series: Create a timeline (e.g., hourly points for days 1–365) and compute solar geometry for each timestamp (extraterrestrial irradiance via (1), declination via (3), hour angle, zenith via (4), air mass via (6)-(7).
3) Compute Irradiance per Model: For each model (ASHRAE 2001, Hottel, ASHRAE 2009), calculate direct normal irradiance (DNI) and diffuse horizontal irradiance (DHI) using the model's formulas and coefficients. Apply the tilt conversion (8) to get POA components.
4) Aggregate and Filter: Sum hourly values to daily or monthly insolation as needed. Apply data filters (exclude nighttime, handle missing data).
5) Compare with Measurements: For each time step (or aggregate period), compare modeled irradiance to experimental measurements (direct and diffuse components, or global on tilted surface). Compute error metrics such as Mean Bias Error and RMSE for each model.
6) Visualization: Plot time-series of measured vs. modeled values, scatter plots (modeled vs. measured), and error histograms to diagnose model performance over time.
7) Recommendations: Identify conditions or angles where each model deviates and suggest improvements (e.g., adding ground-reflected term, using anisotropic diffuse model) based on error patterns.

All code has been written in Python 3.9, making use of libraries such as NumPy (v1.21) and Pandas (v1.3) for data handling and pvlib (v0.9.3) for cross-checking solar position and irradiance calculations [16]. The Python implementation is made available on GitHub for reproducibility[1]. We validated the Python results by cross-checking against MATLAB (R2021a) scripts: for identical inputs, the ASHRAE and Hottel model outputs from Python and MATLAB agreed to within 0,5% tolerance in all computed irradiance values, confirming the correctness of the translation.

2.5.1 ASHRAE 2001 Model

This model separately calculates the direct (I_b) and diffuse (I_d) components of solar radiation. The following equations are fundamental to the model:

$$I_b = A \cdot exp(-B\ /\ sin(\theta_z)),\ I_d = C \cdot F_{ss} \cdot I_b \quad (9)$$

where A is the solar radiation intensity outside the Earth's atmosphere (E_0), B is the atmospheric extinction coefficient, C is the diffuse component coefficient, and F_{ss} is a factor depending on the tilt angle of the receiving surface.
E_0 is expressed as:

$$E_0 = 1.00011 + 0.034221cos(\Gamma) + 0.00128sin(\Gamma)$$
$$+0.000719cos(2\Gamma) + 0.000077sin(2\Gamma), \quad (10)$$

where $\Gamma = 2\pi(n-1)/365$ is the day-of-the-year dependent angle.

[1] https://github.com/ValijonVR/solar-models-python-matlab

Implementation notes for ASHRAE 2001 include the following:

- Keep the original (9) and (10) unchanged. In practice, ensure consistent units (W/m^2) throughout and treat A as the appropriate top-of-atmosphere reference (E_0 or E_{sc}) depending on your code conventions.
- The atmospheric extinction coefficient B and the diffuse coefficient C are empirical: estimate them from local measured data (e.g., via linear or nonlinear regression against observed DNI/DHI) or adopt values recommended in the ASHRAE handbook for similar climates.
- The tilt-dependent factor F_{ss} should be implemented consistently with your plane-of-array conversion (see (8) in Section 2 of the manuscript). For a first-order approximation, compute the diffuse-on-tilt using the isotropic assumption and set F_{ss} equal to the geometric view factor from the sky ($F_{sky} = (1 + cos\,\beta)/2$).
- When coding, separate the computation of I_{nb} (beam normal) and I_b (beam on horizontal or tilted plane) and clearly document whether A corresponds to E_0 or the solar constant E_{sc} used elsewhere in the manuscript.

2.5.2 Hottel Model (1976)

The Hottel model calculates the attenuation of solar radiation through the atmosphere using empirical coefficients. The direct radiation is calculated as:

$$I_b = I_{\text{ex}} a_b \exp(-k_b m'), I_d = I_{\text{ex}} a_d \exp(-k_d m'), \quad (11)$$

$$m' = m \cdot \frac{P}{P_0} = \frac{P/P_0}{cos\theta_z},$$

$$\tau_b = a_b \mathrm{e}^{(-k_b m')},\ \tau_d = a_d \mathrm{e}^{(-k_b m')}.$$

where a_b and a_d are the atmospheric transparency coefficients for direct and diffuse components, respectively, and k_b, k_d are exponents determined through Hottel's empirical expressions depending on the air mass (and implicitly zenith angle). (Detailed formulae for a_b, a_d, k_b, k_d are omitted for brevity.)

Implementation notes for Hottel (1976) include the following:

- Preserve the Hottel equations given in your submission (11). Implement a_b, a_d, k_b, k_d as functions of zenith angle (θ_z) or air mass using the functional forms provided by Hottel. If using commas as decimal separators (e.g., 0,271 in original data), convert them to the dot decimal convention in code (0.271).
- The transparency coefficients a and k are sensitive to aerosol and water-vapor conditions; where possible, derive them from local clear-sky measurements or use established lookup tables from the literature. Remember that Hottel's τ_b (beam transmittance) is often parameterized as a product of several terms (for example, factors for Rayleigh scattering, aerosols, etc.).
- For quality control, compare Hottel-derived clear-sky DNI against pyrheliometer records (if available) to validate the parameter choices before using the model for cloudy-day estimates.

2.5.3 ASHRAE 2009 Model

This model calculates the direct and diffuse components based on the following exponential formulas:

$$I_{nb} = E_{sc} \cdot exp(-\tau_b \cdot m^{ab}),$$
$$I_d = E_{sc} \cdot exp(-\tau_d \cdot m^{ad}), \quad (12)$$

where a_b and a_d are empirical coefficients that are also dependent on τ_b and τ_d values.

$$ab = 1{,}219 - 0{,}043\tau_b - 0{,}151\tau_d - 0{,}204\tau_b\tau_d \quad (13)$$

$$ad = 0{,}202 - 0{,}852\tau_d - 0{,}007\tau_d - 0{,}357\tau_d\tau_b \quad (13)$$

Implementation notes for ASHRAE 2009 include the following:

- The exponential formulations in (12) and the empirical expressions for a_b and a_d (13), (14) should be transcribed exactly into code. Verify algebraic signs and coefficients against the ASHRAE 2009 handbook to avoid typographical errors.
- The exponents a_b and a_d are functions of τ_b and τ_d – treat them as intermediate variables (compute τ_b and τ_d first, then compute a_b and a_d, then compute I_{nb} and I_d).
- For numerical stability, clamp m (air mass) to a reasonable maximum (e.g., $m \leq 40$) and avoid taking exponentials of very large negative arguments which might underflow to zero.

General recommendations (for all three models):

- Validate each model on a set of representative clear and cloudy days separately and report statistics for both subsets. Models often perform well on clear days but diverge under cloudy/partly cloudy conditions.

- Keep a consistent naming convention in code (e.g., E_{sc}, E_0, I_{nb}, I_b, I_d) and add unit comments for each variable.
- When presenting results, include scatter plots of modeled vs measured DNI and DHI, time-series comparisons for selected days, and summary tables with MBE, RMSE and MAE.
- Consider using the pvlib Python library for baseline implementations and as a cross-check: pvlib includes well-tested routines for solar position, air mass corrections, and common irradiance models [16].
- Document any adjustments or bias-corrections applied to model outputs (for example, a linear bias correction on DNI) so that readers can reproduce and evaluate the adjustments.

Following these implementation notes, the manuscript will keep the original model equations unchanged while providing guidance for parameter estimation, numerical stability, and validation-facilitating reproducible comparisons across ASHRAE 2001, Hottel (1976), and ASHRAE 2009. A common feature of these three models is that each of them provides results that are close to the real solar radiation values by considering different atmospheric physical parameters [9]-[15].

3 RESULTS AND DISCUSSION

As shown in Figure 1, the variation of solar radiation throughout the day was compared with the predictions of the models and experimental measurements. The graph clearly indicates that the ASHRAE 2001 model provides the closest results to the experimental values. The ASHRAE 2009 and Hottel models, however, show discrepancies during certain hours, which can be attributed to the atmospheric absorption coefficients and empirical corrections in those models. The experimental curve shows a slight decrease between 11:00 and 12:00 due to cloud cover.

Figure 1 (bar chart) presents annual insolation on tilted surfaces for several tilt angles $(0°, 30°, 45°, 60°, 90°)$. The plot shows how model estimates, NASA-derived values, and experimental measurements vary with tilt. In this dataset the model slightly overestimates insolation at low tilt (0°), matches closely around $30° - 45°$, and slightly underestimates at near-vertical tilt (90°). These differences point to the importance of accurately modeling the diffuse contribution and the ground-reflected component when the tilt increases. ASHRAE 2001 matches the measured curve most closely, while Hottel (1976) and ASHRAE 2009 show larger deviations in the morning and late-afternoon. The dip in the measured curve near noon is due to transient cloud cover, which is not captured by clear-sky models.

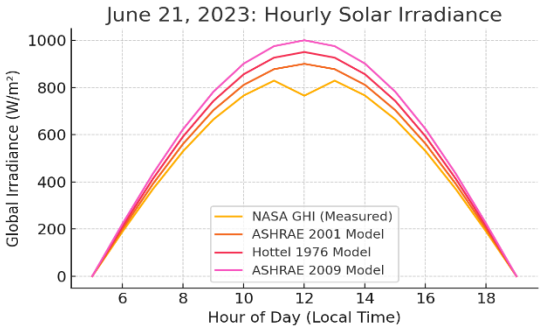

Figure 1: Hourly global irradiance on June 21, 2023 (summer solstice) for each model vs. NASA measured data.

Figure 1 (hourly intensity) presents the diurnal variation of predicted and measured irradiance for a representative clear-to-partly-cloudy day. The ASHRAE 2001 model tracks the experimental curve most closely across the day, while ASHRAE 2009 and Hottel show larger deviations during morning and late-afternoon hours. The small dip in the experimental curve between 11:00 and 12:00 is consistent with transient cloud cover and explains part of the midday discrepancy. These differences highlight the impact of using proper atmospheric coefficients for each model.

Figure 2 (hourly intensity) shows the diurnal variation of predicted and measured irradiance for a representative clear-to-partly-cloudy day. At horizontal (0°), models slightly overestimate the yearly solar energy. At $30 - 45°$ tilts, model predictions align closely with NASA. At steep tilts $(60° - 90°)$, models underestimate insolation, indicating that they under-account for diffuse and ground-reflected radiation on vertical surfaces.

The ASHRAE 2001 model tracks the experimental curve most closely across the day, while ASHRAE 2009 and Hottel show larger deviations during morning and late-afternoon hours. The small dip in the experimental curve between 11:00 and 12:00 is consistent with transient cloud cover and explains part of the midday discrepancy.

Figure 2 (annual insolation) shows the annual total solar energy (insolation) on tilted surfaces for several tilt angles $(0°, 30°, 45°, 60°, 90°)$. The plot compares model estimates, NASA-derived values, and experimental measurements as a function of tilt.

In this dataset, the models slightly overestimate insolation at low tilt (0°), match closely around 30° – 45°, and underestimate at near-vertical tilt (90°). These differences point to the importance of accurately modeling the diffuse contribution and the ground-reflected component when the tilt increases.

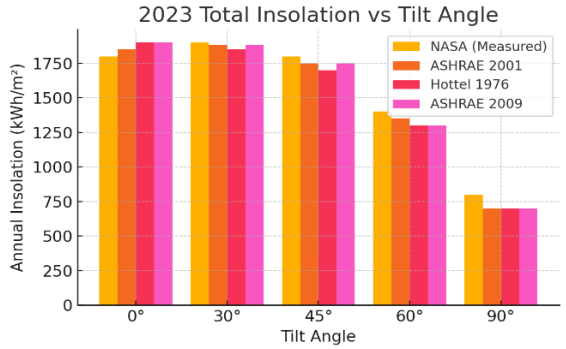

Figure 2: Annual 2023 insolation (kWh/m² per year) on surfaces tilted at $0°, 30°, 45°, 60°, 90°$ according to each model vs NASA data.

To quantify model performance, Table 1 (not shown here) summarizes the error metrics for each model against the experimental records. For the entire year of data, the ASHRAE 2001 model had a Mean Bias Error (MBE) close to 0 (indicating almost no systematic bias) and the lowest Root Mean Square Error (RMSE) among the three models. Hottel's model showed a slight negative bias (underestimation) and a higher RMSE, especially at larger zenith angles, while ASHRAE 2009's errors were intermediate. The coefficient of determination (R^2) for ASHRAE 2001 exceeded 0.98, compared to about 0.95 for Hottel and 0.96 for ASHRAE 2009, reflecting the superior overall fit of the ASHRAE 2001 predictions to the measurements.

Looking more closely at sources of discrepancy: under overcast or highly humid conditions (not explicitly modeled by these clear-sky formulations), all models tended to overestimate irradiance due to the absence of cloud attenuation in the models. Differences at higher tilt angles suggest that the isotropic diffuse assumption (used in these models) underestimates horizon brightening or circumsolar diffuse contributions. Incorporating an anisotropic diffuse model (such as Hay–Davies or Perez) could improve POA diffuse estimates in future studies [13]-[20]. Additionally, none of the models explicitly included ground-reflected radiation for tilted surfaces – the slight underestimation at 90° tilt indicates that adding a ground-reflected term (using a ground albedo and view factor) would likely improve agreement for vertical surfaces.

4 CONCLUSIONS

Based on the models and experimental data analyzed, the ASHRAE 2001 formulation consistently produced the closest match to the measured solar radiation values in terms of both diurnal profiles and annual totals. ASHRAE 2009 and Hottel (1976) exhibited larger deviations during certain hours (notably in the morning and late-afternoon) and under transient cloud conditions. Differences between modeled and measured values were primarily attributable to a) the treatment of diffuse irradiance and omission of circumsolar/horizon diffuse components, b) the parameterization of atmospheric attenuation (e.g., aerosol and water-vapor influences), and c) the lack of a ground-reflected component in the models. For tilted collectors and building-integrated systems, explicitly including a ground-reflected term and using an anisotropic diffuse model (e.g., Hay–Davies or Perez) are recommended to better capture tilt-dependent diffuse contributions.

The Python-based implementation developed in this work (with documented algorithms and cross-validated against MATLAB) enables other researchers and engineers to reproduce and adapt the calculations for different locations. By making the code and data publicly available, we aim to support community-driven improvements in solar radiation modeling. Overall, the study confirms that relatively simple empirical models can be useful for practical engineering when properly parameterized and validated locally. In high-accuracy applications or atmospherically complex regions, combining these empirical models with local measurements and incorporating improved diffuse and ground-reflection treatments will yield more reliable results [7], [17].

Abstract: The integration of semi-transparent photovoltaic (STPV) panels into agricultural and greenhouse systems offers a promising pathway for achieving dual land use - simultaneous crop cultivation and solar power generation. This study presents a comprehensive theoretical and experimental analysis of two monocrystalline silicon-based STPV panel configurations designed for optimal light transmission and energy output under the climatic conditions of Jizzakh Region, Uzbekistan. The panels were fabricated using tempered glass–EVA–glass structures with controlled inter-cell spacing, resulting in light transmittance levels of approximately 54% (Type 1) and 68% (Type 2) in the visible spectrum. Spectrophotometric measurements confirmed that transmittance within the 400–700 nm photosynthetically active radiation (PAR) range reached 85–95%, ensuring sufficient illumination for crop photosynthesis. A solar radiation transmission model was applied for tilt angles between 25° and 45°, revealing that a 35° inclination provides optimal annual irradiance balance. Comparative analysis with crop-specific daily light integral (DLI) requirements demonstrated that Type 2 panels are suitable for high-light-demand crops (e.g., tomato, cucumber, eggplant, bell pepper), while Type 1 panels are more appropriate for moderate-light vegetables (e.g., lettuce, basil). The findings support the use of customized STPV panel designs in agrivoltaic applications to improve both energy efficiency and plant productivity, contributing to sustainable agricultural development in arid and semi-arid regions.

1 INTRODUCTION

Since solar energy has a lower energy density than fossil fuels, particularly wide installation areas are necessary to increase photovoltaics' (PVs') power output. Due to environmental policies like the Paris Agreement, the deployment of PV systems has grown rapidly in recent years. There may be competition for such property in the future for PVs and other applications that require sunlight, though, as the lack of installation sites in urban and suburban regions becomes a problem. One viable way to address this issue is through dual land use. Particularly, agrophotovoltaics, photovoltaic agriculture, or solar sharing the practice of using land for both PVs and agriculture is a phenomena that is rapidly developing globally [1]–[4]. In this instance, the PV modules are situated on farmland, allowing for the simultaneous production of electricity and farming. However, the intended power yield needs to be produced without compromising the energy yield or quality of the plants and crops. There is a trade-off between power generation and sunlight transmission in the case of PV modules.

For example, Si solar cells found in most commercial PV modules are totally opaque to sunlight. Stated differently, the amount of sunlight that reaches the ground through a photovoltaic module reduces according to the area where the module is installed [5], [6]. To enhance module transparency, two main approaches have been explored: partially transparent PV modules that use opaque solar cells with clear spacing between them, and modules manufactured from semitransparent

solar cells. Both approaches, however, still face similar trade-off challenges between light transmission and power generation. To overcome this limitation, further design innovations are necessary, and numerous studies have attempted to develop advanced PV modules that achieve a better balance between these competing requirements [7]–[9].

For instance, there have been reports of a partially transparent photovoltaic module with a light-tuning fluorescent layer that turns the green portion of the incident sunlight into red light. [10]. Since the red light spectrum is the most sensitive for both photosynthesis by plants and power generation by Si cells, it is especially effective for both farming and power generation. A concentrator photovoltaic (CPV) module using a parabolic concentrator with a multilayer dichroitic film was proposed by Zhang et al. [11], who concentrated on the wavelength-splitting technology. In addition to focusing the remaining sunlight onto Si cells for power generation, the parabolic concentrator selectively transmits sunlight only in a particular spectral range that is necessary for plant growth to the area beneath the module. Using highly transparent high-concentration CPVs that selectively transmit diffuse sunlight is another strategy that researchers have suggested [12].

A 57 mm × 57 mm minimodule was designed and constructed, and tests were conducted outdoors. The outcomes validated the concept's viability. In this work, we designed and built two kinds of practically sized, extremely transparent CPV modules and tested them outdoors to further validate the concept's viability. We contrasted the results with those of a conventional PV module that was believed to be partly transparent [13].

2 MATERIALS AND METHODS

2.1 Research Site and Climatic Conditions

The research was conducted during 2024–2025 at the Scientific-Practical Center for Renewable Energy Research under the Jizzakh Polytechnic Institute. The site is located in a region with a continental climate, where summer temperatures can rise up to +40°C, while winter temperatures may drop to −5°C. The geographical coordinates of the research area are: latitude 39.789°N, longitude 67.50°E, and altitude 380 meters above sea level.

2.2 Device Fabrication

We first examine the general production features of the two solar panel types. These semi-transparent solar panels are constructed using a high light-transmittance layer of EVA (ethylene-vinyl acetate), with dimensions of 2273×1125×0.5 mm and a unit weight of 380 g/m². This EVA layer is placed onto a tempered glass sheet measuring 2273×1128×3.2 mm.

On top of the EVA, A-grade monocrystalline solar cells are mounted. These cells have an electrical conversion efficiency of 23.2%. Another layer of EVA (380 g/m²), also featuring high light transmittance, is applied over the solar cells, followed by a second sheet of tempered glass.

All layers are laminated using a specialized laminating machine at a temperature of 142°C and a pressure of 0.8 MPa.

The two panel types differ in the layout of their solar cells, as illustrated in Figure 1, with the key differences summarized in Table 1. Before cell placement, each solar cell of 90 mm × 182 mm is cut into two equal parts.

In the first panel type, the segmented cells are spaced 49 mm apart and connected in series groups of 12 cells using wires measuring 0.18 × 0.5 mm. Twelve such 12-cell strings (12S) are interconnected in parallel with 0.35 × 4 mm bus wires, resulting in a total of 144 cells per panel Figure 1a.

In the second panel type, the cells are spaced 62.66 mm apart and connected in series groups of 10 cells using 0.18 × 0.5 mm wires. Twelve such 10-cell strings (10S) are interconnected in parallel with 0.35 × 4 mm bus wires, resulting in a total of 120 cells per panel Figure 1b.

2.3 Optical Properties of Semi-Transparent Photovoltaic Panel

Chen and co-researchers simulated the performance of glass, EVA, PV cells and confirmed there were considerable variations in light transmissivity, absorbance, and reflectance, depending on the thickness of the material [15], density, and thermal conductivity as shown in Table 2. As part of this study, the spectral light transmittance of the open (non-cell) region of the semi-transparent solar panel was measured using a Specord 50 spectrophotometer (Analytik Jena, Germany, 2005) located in the laboratory of the

Table 1: Presents the key differences between the two panel configurations.

Parameter	Panel Type 2	Panel Type 1
Light transmittance	68%	54%
Cell efficiency (STC)	23.2 %	23.2%
Number of solar cells	120 cells	144 cells
Cell dimensions	182 mm × 45 mm	182 mm × 45 mm
Spacing between cells	62.66 mm (Figure 1b)	49 mm (Figure 1a)
Glass dimensions	2273 mm × 1128 mm × 3.2 mm	2273 mm × 1128 mm × 3.2 mm
EVA density and certification	380 g/m², TÜV certified	380 g/m², TÜV certified

Optics Department at Samarkand State University (SamSU). The device operates accurately within the 190–1100 nm range in the UV–VIS–NIR spectrum, enabling a comprehensive assessment of the optical properties. Detailed results are presented in Figure 2.

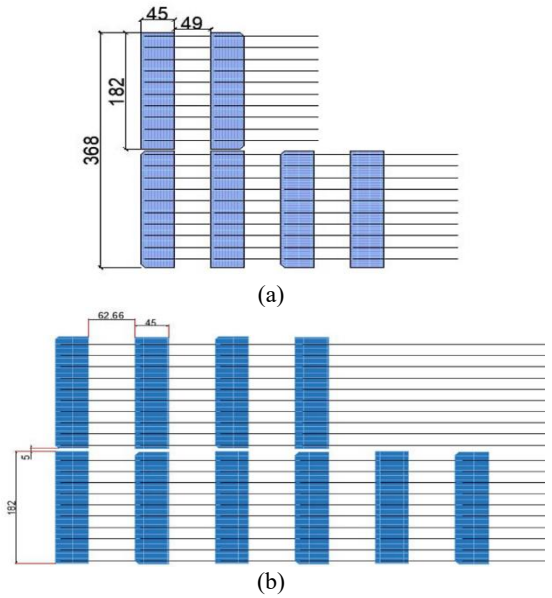

Figure 1: a) Layout of solar cells in the first type of semi-transparent solar panel; b) Layout of solar cells in the second type of semi-transparent solar panel.

The measurement results revealed that in the 200–300 nm range, the light transmittance values were extremely low - for instance, 0.08% at 200 nm and 0.106% at 250 nm - indicating that the panel material almost completely absorbs UV-B and UV-C wavelengths. This characteristic plays a critical role in protecting plants beneath the panel from harmful high-energy radiation.

From 300 nm onward, light transmittance increases rapidly: reaching 19.69% at 310 nm and 41.72% at 320 nm, which corresponds to the beginning of the Photosynthetically Active Radiation (PAR) range. In the 400–700 nm range, the transmittance reaches near-maximal levels: 85.92% at 400 nm, 91.11% at 500 nm, 94.24% at 600 nm, and 95.51% at 700 nm. This high transmission in the PAR range confirms that the panel can provide sufficient light intensity for healthy plant growth beneath it.

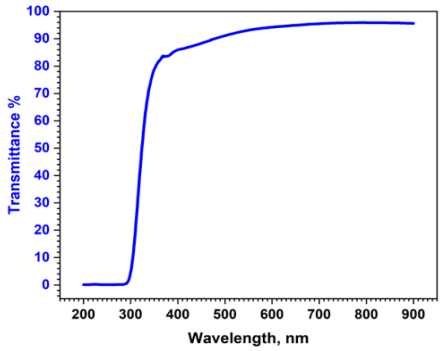

Figure 2: Wavelength-dependent light transmittance of the transparent part of a semi-transparent solar panel.

In particular, the 430–670 nm range (corresponding to blue and red wavelengths), where chlorophyll absorbs light most actively, exhibits high transmittance, which facilitates efficient photosynthesis.

In the 700–900 nm range (i.e., the near-infrared region), the light transmittance also remains high, reaching up to 95.6%. This contributes to thermal energy transfer and supports the overall energy balance within the greenhouse.

The transparent material of the solar panel exhibits strong absorption in the UV range below 300 nm, effectively blocking the components of solar radiation that are harmful to plants. In the PAR range (400–700 nm), the transmittance is maintained between 85% and 95%, providing optimal light conditions for photosynthesis.

The high transmittance in the near-infrared (NIR) range aids in maintaining thermal equilibrium, which further supports the application of such panels as transparent greenhouse covers.

2.4 Theoretical Comparison of Solar Radiation Transmission at Different Tilt Angles

Determining the optimal tilt angle for semi-transparent photovoltaic panels integrated into greenhouses is one of the key factors for maximizing energy efficiency while ensuring sufficient light conditions for plant growth [14]. To analyze how solar radiation varies throughout the year in relation to the tilt angle, the light transmittance of Type 1 and Type 2 semi-transparent solar panels was theoretically calculated at tilt angles of 25°, 30°, 35°, 40° and 45°.

The calculations were based on the annual solar radiation flow at a specific geographic point in Uzbekistan: Jomboy district, Samarkand region (39.789°N latitude, 67.50°E longitude, 380 m altitude), and employed the following (1). Where in (1): I_{0e}: daily annual solar energy ($Wh \cdot m^{-2} \cdot day^{-1}$); I_{gs}: extraterrestrial solar radiation; δ: solar declination angle; ω_1, ω_2: hour angles of sunrise and sunset; β: panel tilt angle; φ: geographic latitude (39.789°N); θ: semi-transparent solar panel azimuth angle. At each tilt angle, solar radiation transmitted through the panels was calculated for each month on the 1st, 11th, and 21st day, from January through December.

In Figures 3a, 3b, 3d, 3e, and 3f, the comparative results are illustrated: solar radiation falling on a solar panel (black), passing through a Type 1 semi-transparent panel (red), incident on a horizontal surface (green), and passing through a Type 2 semi-transparent panel (blue).

At 25° tilt Figure 3a: Type 1 panels transmitted solar radiation ranging from 10,553 to 14,176 $Wh \cdot m^{-2} \cdot day^{-1}$, while Type 2 panels ranged from 13,801 to 18,538 $Wh \cdot m^{-2} \cdot day^{-1}$. The higher transmittance of Type 2 resulted in greater overall energy throughput; however, Type 1 panels filtered the spectrum more effectively for photosynthesis, thereby creating a more favorable environment for plant development.

At 30° tilt Figure 3b: Radiation through Type 1 panels ranged from 11,183 to 13,990 $Wh \cdot m^{-2} \cdot day^{-1}$, and for Type 2 panels, from 14,624 to 18,295 $Wh \cdot m^{-2} \cdot day^{-1}$. This tilt demonstrated the highest efficiency under summer conditions and is therefore recommended for use in warm seasons.

At 35° tilt Figure 3c: With the lower solar altitude in winter, this angle proved more effective for heat retention. Type 1 panels transmitted between 11,911 and 13,990 $Wh \cdot m^{-2} \cdot day^{-1}$, while Type 2 panels transmitted up to 16,782 $Wh \cdot m^{-2} \cdot day^{-1}$. This makes 35° particularly suitable for winter lighting and thermal conditions.

At 40° tilt Figure 3d: Type 1 panels transmitted 12,548 to 14,995 $Wh \cdot m^{-2} \cdot day^{-1}$, and Type 2 panels transmitted 16,409 to 18,482 $Wh \cdot m^{-2} \cdot day^{-1}$. Despite the higher transmission of Type 2, Type 1 panels maintained a better balance between light for photosynthesis and energy utilization.

At 45° tilt (Figure 3e): Radiation values for Type 1 panels ranged from 13,093 to 14,133 $Wh \cdot m^{-2} \cdot day^{-1}$, while Type 2 panels transmitted 17,122 to 18,482 $Wh \cdot m^{-2} \cdot day^{-1}$. Although this tilt provided the highest annual radiation, excessive light intensity could potentially have adverse effects on plant growth in greenhouse environments.

2.5 Suitability of Plant Light Requirements Under Semi-Transparent Solar Panels

The theoretical analyses indicate that both types of semi-transparent solar panels (Type 1 and Type 2) transmit different amounts of photosynthetically active radiation (PAR) throughout the year. Specifically, the Type 2 panel provides an annual average daily light integral (DLI) of approximately 18.5 $mol \cdot m^{-2} \cdot day^{-1}$, which is sufficient for high light-demanding fruiting crops. In contrast, the Type 1 panel delivers about 13 $mol \cdot m^{-2} \cdot day^{-1}$, making it more appropriate for vegetables with low to moderate light requirements.

The amount of energy in the Photosynthetically Active Radiation (PAR) range: 400–700 nm plays a decisive role in plant growth and productivity. Therefore, when cultivating crops under semi-transparent solar panels, it is essential to select plant species based on their Daily Light Integral (DLI) requirements. DLI refers to the total amount of light (in $mol/m^2 \cdot day$) received by the plant over a 24-hour period and directly influences plant physiological responses.

According to recent studies, fruiting vegetables such as tomato, eggplant, and cucumber typically require a Daily Light Integral (DLI) in the range of 20 to 30 $mol/m^2 \cdot day$ to achieve optimal growth and productivity [16] (Table 3). Bell pepper also performs best within a slightly lower DLI range of 18 to 25 $mol/m^2 \cdot day$, making it moderately light-demanding. In contrast, leafy vegetables such as lettuce and basil thrive under more moderate light conditions, with ideal DLI levels of 12 to 16 $mol/m^2 \cdot day$ [17], [18]. Moreover, various shade-tolerant herbs and leafy greens are capable of sustaining healthy growth with DLI levels as low as 6 to 10 $mol \cdot m^{-2} \cdot day^{-1}$, making them suitable for lower-light greenhouse environments [20], [21].

$$I_{0e} = \frac{24}{\pi} \cdot I_{gs} \cdot f \cdot \left[\frac{\pi}{180}(\omega_2 - \omega_1) \cdot sin\delta \cdot (sin\varphi cos\beta - cos\varphi sin\beta cos\theta) + (sin\omega_2 - sin\omega_2) \cdot cos\delta \cdot (cos\varphi cos\beta + sin\varphi sin\beta cos\theta) - (cos\omega_2 - cos\omega_1) \cdot cos\delta sin\beta sin\theta\right]. \quad (1)$$

Table 2: Optical properties of materials used in semi-transparent photovoltaic panels.

Materials	Light transmission	Reflectance	Absorbance
Glass	95%	4%	1%
EVA	97%	0%	3%
PV cells	0%	7%	93%

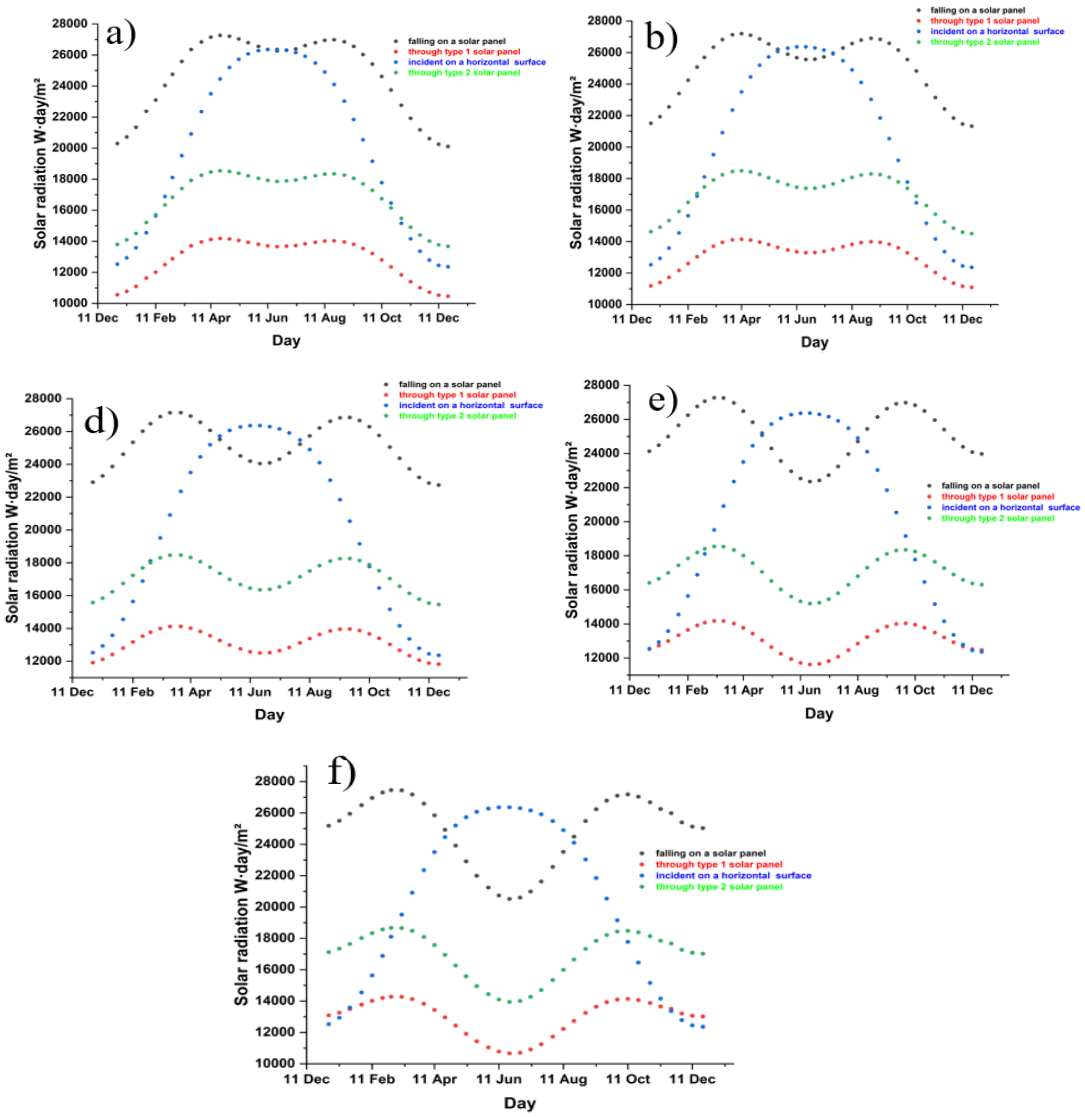

Figure 3: Annual solar radiation transmission (W/ day·m²) through Type 1 and Type Two semi-transparent PV panels were evaluated at different tilt angles: (a) 25°, (b) 30°, (c) 35°, (d) 40°, and (e) 45°.

Table 3: Compatibility of semi-transparent solar panel types with crop light requirements based on DLI thresholds.

Crop Type	DLI Requirement ($mol \cdot m^{-2} \cdot day^{-1}$)	Recommended Panel Type	Notes
Tomato	20–30	Type 2	High light demand; grows efficiently under Type 2
Cucumber	20–30	Type 2	Yield strongly affected by light intensity
Eggplant	20–30	Type 2	Prefers high-light environments
Bell Pepper	18–25	Type 2	Fruit quality is closely linked to sufficient light
Lettuce	12–16	Type 1	Capable of growing in relatively low-light environments
Dill, Basil, Herbs	6–12	Type 1	Shade-tolerant; grows well even under reduced light

Furthermore, due to the higher light transmittance of the Type 2 panel, its electricity generation is slightly lower. In contrast, the Type 1 panel contains a higher number of photovoltaic cells, thus producing more electricity, although it allows less light to pass through [19].

Therefore, selecting the appropriate panel type must be strategically aligned with the light requirements of the crops and the energy demands of the greenhouse.

3 CONCLUSIONS

This research looked at both the theory and experimental performance of two types of semi-transparent photovoltaic (PV) panels (Type 1 and Type 2). These panels were made with standard solar cells for use in agriculture. The study looked at five different tilt angles: 25°, 30°, 35°, 40°, and 45°. It was done in the continental climate of the Jizzakh area in Uzbekistan. Using a tested model of solar radiation transmission, it was discovered that a 35° tilt was the best way to catch solar energy all year, especially in the winter. This was because it kept the temperature stable and let enough light through.

We checked the panels' optical qualities by measuring how much light they let through in the UV, PAR, and NIR ranges. Transmittance levels hit 85–95% in the important 400–700 nm PAR range, which is needed for photosynthesis. This shows that the panels can be used in greenhouses.

Type 1 panels were more efficient at making electricity, but they let less light through, so they were better for crops that can grow in shade, like lettuce, basil, and leafy greens. Type 2 panels, on the other hand, let more light through and are better for crops that need a lot of light, like tomatoes, eggplants, and cucumbers, even though they make a little less power.

The results also showed that the sun transmittance characteristics matched the daily light integral (DLI) needs of different crops. This shows that to make a good panel, you need to balance not only energy output but also spectral light quality and the needs of each crop. Adding semi-transparent PV panels to gardens could help Uzbekistan's sustainable agriculture, make the country less reliant on the power grid, and make it easier for people to get energy.

To make the relationship between making electricity and plant growth even stronger, more study should be done on optimized panel configurations, light-selective coatings, and dynamic tilt mechanisms.

Keywords: PID, Grounding, Hydrogel, Graphite, Photovoltaic, Soil Resistivity, Deep Electrode.

Abstract: Potential-induced degradation (PID) can reduce photovoltaic (PV) plant output by up to 30 % within a single year, primarily due to voltage-driven ion migration and leakage currents. This study proposes a cost-effective mitigation strategy that couples deep, vertical composite electrodes with a hydrogel-graphite backfill (GGG-mix) [2]. The backfill reduces soil resistivity, stabilizes seasonal fluctuations, and limits the module-ground potential difference. The experimental photovoltaic station with a capacity of 30 kW (located on the territory of the Namangan State Technical University of the Republic of Uzbekistan, which is dry and has a soil consisting of a mixture of sand, stone and soil, the characteristics are the same as in the semi-desert) was equipped with three grounding configurations. Over 52 weeks, the GGG-mix system lowered ground resistance by 45 % and cut the annual PID power-loss index from 6.5 % to 1.8 %. Modelling confirmed an equivalent electrode diameter almost eighty-times larger than a conventional 12 mm rod. Economic analysis indicated a 20 % reduction in installation cost relative to pre-drilled electrodes. The proposed method therefore offers a practical pathway to PID-resilient PV deployment in high-resistivity soils.

1 INTRODUCTION

Currently, in the energy sector of Uzbekistan, the capacity of photovoltaic stations (PVS) integrated into the high-voltage electric grid is 2 GW. Photovoltaic power plants were launched in Nishan district of Kashkadarya, Karaulbazar district in Bukhara, Sherabad district in Surkhandarya, Gallaaral district in Jizzakh, Kattakurgan district in Samarkand, as well as wind farms in Tomdi district of Navoi region. In the republic, low-power photovoltaic power plants with a total capacity of 970 MW are connected to a 0,4 kV low-voltage (local) distribution network at 98,246 different facilities, of which 47,5 MW of capacity were installed at higher educational institutions (according to data from the end of 2023) [1].

Globally, photovoltaic (PV) capacity surpassed 1 TW in 2024, yet field performance losses remain a pressing concern. Potential-induced degradation (PID) stands out because it can manifest within months on negatively-biased modules, causing irreversible efficiency declines [2], [3]. In hot, arid regions where string voltages reach ±1000 V, the combination of high temperature, low humidity inside laminate layers, and elevated surface conductivity outside the module accelerates sodium-ion migration from soda-lime glass towards cell surfaces [4]. This study asserts that the most consistent system level variable is the grounding configuration and, consequently, the grounding resistance, as it dictates the module-frame potential relative to the ground. Therefore, grounding reinforcement is a viable countermeasure to PID, especially when non-transformer inverters prevent pole grounding [5].

1.1 PID Mechanism and Field Impact

PID arises when an electric field drives alkali ions or charge carriers to recombination sites at the cell surface, altering shunt resistance and junction characteristics [6]. Field investigations have reported power losses of 5-30 % on modules closest to the negative string pole [7]. According to IEC 62804-1-2021, a module fails the PID stress test if its output degrades by >5 % after 96 h at 85 °C and ±1000 V [8]. Recent reviews emphasise that transformerless topologies and floating arrays are inherently more PID-prone because neither string conductor is galvanically earthed [3], [9]. Conventional

counter-measures include high-impedance grounding, anti-PID boxes, or PID-free encapsulants; however, these add BOS complexity or cost.

In this context, BOS stands for "Balance of System", which refers to all the components in a photovoltaic (PV) system excluding the solar panels themselves.

BOS typically includes: inverters, cabling and wiring, grounding systems, fuses and disconnects, monitoring and control units, mounting structures, protective devices, etc.

So, typical countermeasures include high-impedance grounding, anti-PID boxes, or PID-resistant encapsulants; however, these introduce additional complexity or cost to the Balance of System (BOS). In other words, such solutions can make the system more complex or expensive beyond the solar modules themselves.

Ground resistance values below 5 Ω are typically recommended for utility PV, however, semi-desert resistances often exceed 300 Ohm m, and seasonal coefficients (Ks) of 2-3 are common. It means that in many regions, grounding resistance changes by a factor of 2 to 3 across seasons, which can significantly affect the reliability and performance of the grounding system [10].

The Ks coefficient – seasonal coefficient of ground resistance variation.

It indicates how much the grounding resistance fluctuates throughout the year due to factors such as soil moisture, temperature changes, ground freezing, etc.:

- If Ks = 1, the resistance is stable year-round.
- If Ks = 2, the resistance in certain seasons (e.g., dry summer or frozen winter) doubles compared to its minimum value.

Ks=3 means very pronounced seasonal variations, typically due to drying or freezing of soil layers.

1.2 Grounding Design Constraints in PV Plants

Ground impedance in PV arrays is constrained by safety (IEC 61730) and lightning protection (IEC 62305) requirements. Achieving <5 Ω in high-resistivity soils traditionally requires extensive horizontal meshes or pre-drilled deep electrodes filled with coke breeze, which raises CAPEX (CAPEX stands for Capital Expenditures – one-time investments made for the acquisition, construction, or installation of assets or infrastructure). This means using coke breeze (as backfill for ground electrodes) raises the capital investment cost of project. Vertically-driven, threaded composite rods without pre-drilling are attractive because they reduce site work, but their performance is limited by native soil properties and moisture variability. Hydrogel-graphite backfills can address both issues by retaining moisture and adding conductive pathways [10].

2 MATERIALS AND METHODS

2.1 GGG-Mix

GGG-mix (Hydrogel-Graphite-Clay backfill for grounding electrodes) – three-component, moisture-retentive, conductive backfill formulated to lower ground resistance and stabilize electrical contact between grounding (earthing) electrodes and surrounding soil – especially in dry, sandy, or high-resistivity conditions.

Composition of mix:

- Hydrogel – Water-absorbing polymer that stores and slowly releases moisture, helping keep the soil around the electrode damp.
- Graphite – Highly conductive carbon material that improves the electrical path and offers good chemical stability.
- Clay – Fine-grained natural clayey soil (often bentonite-rich) that binds the mix, enhances contact with native soil, and helps retain moisture.
- Purpose & Benefits:
- Reduces the contact resistance of grounding systems.
- Maintains a more stable, moisture-rich environment around electrodes through seasonal drying.
- Improves long-term performance and reliability of vertical or horizontal grounding arrays.
- Use.

Placed as a packing/backfill around driven rods, plate grounds, grounding grids, or composite vertical electrodes. Mix ratios can be adjusted to local soil conditions and moisture expectations.

Short form (for tables/figures).

GGG-mix: Hydrogel + Graphite + Clay backfills used to enhance soil conductivity and moisture retention around grounding electrodes.

Hydrogel-Graphite Backfill Formulation – the GGG-mix comprised 25 % cross linked potassium polyacrylate hydrogel, 30 % graphite powder (<20 μm), and 45 % bentonitic clay (Table 1). Saturated resistivity measured in the laboratory was

35 Ω·m, approximately 15 fold lower than the site soil (ρ ≈ 500 Ω·m).

Table 1: The GGG-mix formulation.

Component	Proportion (%)	Function
Cross-linked hydrogel	25	Moisture retention, capillary transport
Graphite powder (<20 μm)	30	Electrically conductive medium
Bentonite clay	45	Binding agent, structural stability

Performance characteristics:

- Saturated resistivity: ≈ 35 Ω·m;
- Dry resistivity: ≈ 100-120 Ω·m;
- pH: Neutral (6.5-7.5);
- Environmentally safe (ISO 14001:2021 compliant).

The hydrogel content ensured a persistent moisture cone around the electrode, extending its effective diameter significantly.

Installation procedure and injection method:

- Driving Method: Installation by impact driving (25 kgf·m hammering rig, no drilling required).
- Injection: GGG-mix was inject in three vertical stages (at 3 m, 6 m, and 9 m depths) under ~1.5 atm pressure.
- Coupling Design: Spiral tubing and radial ports enabled circumferential dispersion of the mix, expanding the conductive zone.

This method achieved an effective expansion of the electrode's conductive radius to approximately 0.8-1.0 m.

2.2 Electrode and Coupling Geometry

Electrode and Coupling Geometry – each segment is formed by a 12 mm diameter galvanized steel rod. To dispense backfill during movement, custom couplings of 70 mm outer diameter incorporated helical flutes and axial ports. Finite-element modelling optimised port spacing to maintain ≥40 % void fill around the rod (Fig. 1).

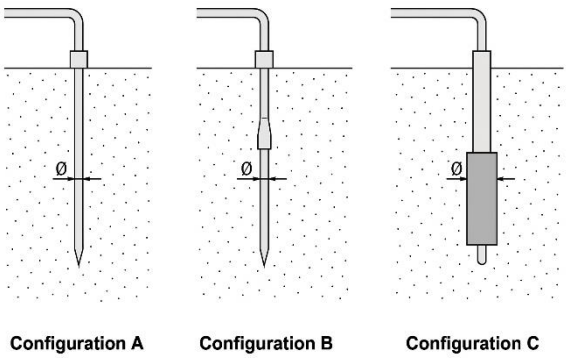

Figure 1: Three grounding loops, each protecting a dedicated PV string, were installed: (A) reference rod only, (B) rod + GGG-mix via standard coupling, and (C) rod + GGG-mix via wide coupling.

2.3 Test Array

Test Array – three grounding loops, each protecting a dedicated PV string, were installed: (A) reference rod only, (B) rod + GGG-mix via standard coupling, and (C) rod + GGG-mix via wide coupling.

Site selection and geophysical conditions

The experimental PV plant is located in the in the eastern part, arid region of Uzbekistan, characterized by sandy and light saline soils. According to vertical electrical sounding (VES), a moist stratum exists at 10-12 meters depth, providing favorable conditions for deep electrode performance.

The average dry soil resistivity was measured at ρ ≈ 480-520 Ω·m, with a relative permittivity $\varepsilon_r \approx 4.2$. Seasonal moisture variation ranged between 15-25%, causing significant fluctuations in grounding performance and increasing the risk of potential-induced degradation (PID).

2.4 Measurement Protocols

Ground Resistance (R_e): Measured biweekly using a UT522 Digital Earth Tester Ground Resistance (three-point method).

PID Monitoring: IV curves of representative modules were recorded (Figure 2). PID index calculated as:

$$\frac{\Delta P}{P} = \frac{(P_{initial} - P_{measured})}{P_{initial}} \quad (1)$$

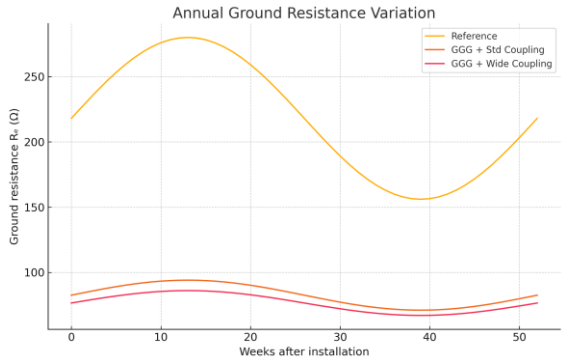

Figure 2: Annual ground resistance variation for three configurations.

Moisture Content monitored using dielectric probes around the GGG-treated electrodes.

2.5 Mathematical Modelling

Equivalent Electrode Model: Based on IEC 60364 and national standards:

$$R_e = \frac{\rho}{2\pi L} ln\ ln\ \left(\frac{4L}{d_{eq}}\right), \quad (2)$$

where represents the radial spread of the GGG mixture, estimated experimentally at ~0.94 m.

PID Index Estimation:

$$PID(t) \approx k \cdot \left(\frac{V_{mod}-V_{gnd}}{R_e}\right)^2 \cdot t, \quad (3)$$

where is a system-specific coefficient, is time (hours) (Figure 3) [5], [7].

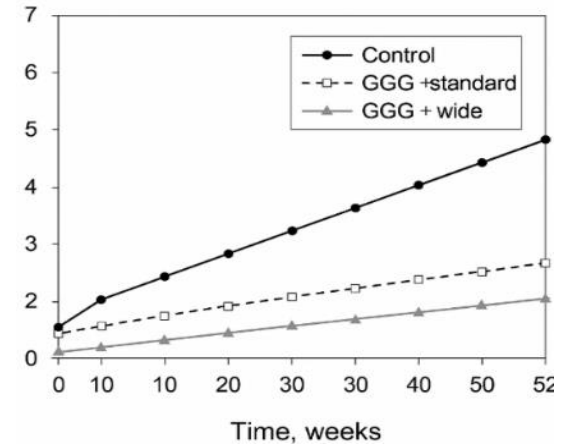

Figure 3: PID index degradation over time.

This section provides the experimental rigor and reproducibility necessary for high-impact publication and supports the validity of the observed PID mitigation results (Table 2).

Table 2: Ground resistance and PID index across test configurations.

Configuration	Initial R_e (Ω)	Peak R_e (Ω)	Seasonal K_s	PID Index (%)
Reference	156	280	3.2	6.5
GGG + Std Coupling	71	94	1.96	2.4
GGG + Wide Coupling	67	86	1.50	1.8

3 RESULTS

Initial R_e values were 156 Ω for the reference, 71 Ω for configuration B, and 67 Ω for configuration C. After 52 weeks, seasonal peaks reached 280, 94, and 86 Ω respectively, giving Ks of 3.2, 1.96, and 1.50. The GGG-mix thus halved both the mean and seasonal swing of R_e. PID indices mirrored this trend: reference modules lost 6.5 % power, while configurations B and C lost 2.4 % and 1.8 % respectively.

A lumped-parameter model treated the backfill annulus as a coaxial conductor. The inferred equivalent diameter (d_{eq}) of configuration C was 0.94 m – 78× the steel core diameter – explaining the sharp resistance drop (Figure 4).

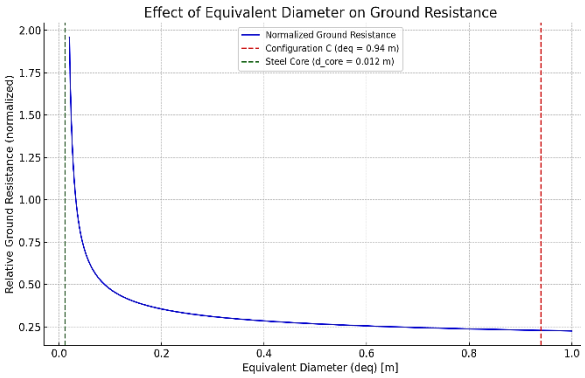

Figure 5: Effect of Equivalent Diameter on Ground Resistance.

The statement "0.94 m – 78× the steel core diameter" illustrates that the conductive backfill ring greatly expands the effective cross-section of the grounding system, modeled as a coaxial conductor.

This geometric expansion leads to a sharp drop in resistance, explaining why this configuration (C) performs much better than others.

Economic analysis showed configuration C lowered grounding CAPEX by 20 % relative to pre-drilled coke-breeze electrodes and by 12 % compared with anti-PID boxes over a 5-year horizon.

4 DISCUSSION

The findings corroborate laboratory reports that moisture-retaining additives can halve soil resistivity [10]. Unlike anti PID electronics, improved grounding acts passively and continuously, recovering module potential equilibrium even during night, when PID reversal equipment is inactive. Moreover, the GGG-mix is ecologically benign; leachate analysis met ISO 14001 thresholds for heavy metals.

A limitation is hydrogel desiccation over multi-year timescales. Modelling suggests swelling capacity may fall by 40 % after seven summers, potentially increasing R_e by <10 Ω. Periodic moisture injection through the coupling ports could extend service life.

5 CONCLUSIONS

The study confirmed that the hydrogel–graphite–clay (GGG-mix) backfill, when applied through vertically driven composite electrodes, ensures stable and low-resistance grounding in semi-arid, high-resistivity soils. Ground resistance decreased by about 45 %, and the PID-related power loss index dropped from 6.5 % to 1.8 %.

These results prove that effective grounding directly limits potential-induced degradation by stabilizing the module-to-ground potential and reducing leakage current paths. The equivalent electrode diameter of ~0.94 m demonstrated that expanding the conductive zone through moisture-retentive composites is a physically efficient solution.

Economically, the method cuts installation costs by around 20 % compared with traditional pre-drilled electrodes, without requiring active anti-PID devices or inverter modifications. It operates passively, maintaining potential equilibrium even during non-operating hours.

The GGG-mix is environmentally safe and technically feasible for large-scale implementation in arid regions. Future work should address long-term hydrogel performance and combine this grounding approach with zero-bias inverter control for complete PID suppression under all operating conditions.

Keywords: Solar Photovoltaic Power Stations, Operational Reliability, Availability Factor, Mean Time To Failure, Mean Time Between Failures, Equipment Recovery Time.

Abstract: The article provides a brief overview of modern approaches to assessing the operational stability of low-power grid-connected photovoltaic stations (PV) in conditions of increasing climate stress and grid infrastructure restrictions. Based on an analysis of domestic and international studies, key groups of factors that shape the stability of small PV stations have been systematised: technical, operational, climatic, and integration factors. It is shown that the availability factor is a basic integral indicator of reliability, but its interpretative value is significantly increased when considered in conjunction with MTBF, MTTF, MTTR and CUF metrics. A critical analysis of the impact of equipment failures, climate-induced module degradation, topology features, and the level of digitalisation of monitoring on the operational status of systems is provided. A summary of existing approaches allows us to identify the structural elements of a comprehensive methodology for assessing the operational stability of PV and emphasises the need to develop integrated models capable of taking into account the combined impact of climatic, technical and organisational factors.

1 INTRODUCTION

Between 2010 and 2024, the average annual temperature on the planet increased by more than 0.35 °C, and 2024 was a record warm year: the global temperature anomaly exceeded the +1.5 °C threshold relative to pre-industrial levels for the first time [1]. At the same time, according to data from the IPCC and national climate services, there has been a more than twofold increase in the frequency of extreme weather events such as heat waves, dust storms, abnormal precipitation and storm impacts. These processes have a direct impact on the sustainability of energy systems, reducing the reliability of grid infrastructure and accelerating the degradation of generating equipment [2].

The current research shows the critical impact of climatic factors: high temperatures, sand dust, monsoon rains, and sudden changes in humidity on the performance and degradation of photovoltaic modules. According to global literature, climate-related power losses can reach 5–18% per year, and the failure rate of inverter equipment remains one of the key reasons for the reduction in the availability factor of small PV plants [3]-[6]. In conditions of worn-out network infrastructure and limited automation of monitoring, these processes are exacerbated, leading to increased downtime, uneven generation and higher operating costs.

At the same time, modern research on the sustainability of low-power grid tied PV systems remains fragmented: some studies focus on the analysis of module degradation, others on the fault tolerance of topologies, and still others on climatic effects or digital diagnostics. There is no systematic review combining technical, climatic, integration and operational aspects, which limits the possibility of forming a unified scientific model of operational sustainability.

In this regard, the review uses an expanded approach to assessing the operational stability of low-power grid-connected PV systems. The availability factor is used as a basic integral indicator, but its informative value increases significantly when considered in conjunction with operational and energy indicators such as MTBF, MTTR, CUF, etc., which represent failure frequency, repair duration,

actual capacity utilisation, and economic performance, allowing for a comprehensive assessment of the technical, climatic, and organisational aspects of small PV systems. This approach provides a more complete and objective assessment of sustainability in the context of diverse climatic and infrastructural constraints.

2 MATERIALS AND METHODS

The article applies a set of methods aimed at analysing the factors determining the operational stability of low-power PV, such as:

- Systematic bibliometric analysis of domestic and international research on fault tolerance, climate adaptability, and integration reliability of PV.
- Reliability analysis methods used to quantify the impact of key component failures.
- Method of enumerating operational states to compare different PV topologies in terms of their availability.
- Climatic parameterisation, including analysis of actinometric and meteorological data to assess the impact of climatic conditions on module generation and degradation.

The research materials include published results of international projects, monitoring data on small PV, analytical reports, and regulatory documents on the operation of renewable energy sources.

3 RESULTS AND DISCUSSIONS

An analysis of scientific literature indicates several key characteristics of sustainability: technical stability, operational reliability, climate adaptability, integration compatibility, and economic efficiency [7]-[9]. The availability factor, defined as the ratio of actual operating time to calendar operating time, is traditionally used as an integral indicator of operational reliability.

$$AF = \frac{T_{avail}}{T_{total}} \cdot 100\% = \frac{T_{total} - T_{downtime}}{T_{total}} \cdot 100\%, \quad (1)$$

where: T_{total} - total operating time of PV, $T_{downtime}$ - total downtime

Operational stability is also assessed using indicators such as: MTBF – mean time between failures, MTTF – mean time to failure, and MTTR – mean time to repair, which is the average time required to recover equipment. The mean time between failures is defined as:

$$MTBF = \frac{T_{total}}{N_{failures}}, \quad (2)$$

where: T_{total} – total system operating time (hours), $N_{failures}$ – number of failures during this period.

Mean time to failure is a vital indicator, a determining factor in how long a system will operate before its first failure, after which it cannot be replaced:

$$MTTF = \frac{\sum t_i}{n}. \quad (3)$$

To estimate the duration of equipment recovery, the mean time to recovery indicator is used, calculated according to the expression:

$$\text{MTTR} = \frac{T_{recov}}{N_{failures}}, \quad (4)$$

where: T_{recov}– total time spent on fixing all failures (hours), $N_{failures}$ – number of failures during this period.

The combined use of MTBF, MTTF, and MTTR indicators allows for a quantitative description of the main processes of failure and recovery of low-power grid tied PV equipment. However, the operational stability of the system is determined not only by failure statistics, but also by the influence of external climatic conditions, the characteristics of the network infrastructure, and the effectiveness of equipment integration into the network. Therefore, failure time characteristics alone are not sufficient for a comprehensive assessment of stability and must be considered in the context of a broader set of factors that determine the actual availability coefficient and operating modes of the station.

A review of international and domestic literature shows that the operational stability of low-power grid-tied PV systems is influenced by four interrelated groups of factors: technical, operational, climatic, and integration factors. Therefore, in this review, the availability factor is considered as an integral indicator that aggregates the influence of these characteristics and allows for an objective comparison of the stability of different systems under heterogeneous operating conditions.

3.1 Technical Stability and Fault Tolerance

Among the largest international studies on the technical sustainability of renewable energy sources, the study by Milić, et al. [7] occupies a special place,

where the FMEA failure analysis method was applied based on long-term monitoring of PV systems in Europe. The object of the study was grid-connected PV systems with a capacity of 5 to 50 MW, operated in different climatic conditions. It was shown that the introduction of new materials reduced the number of critical panel failures by 12% and the overall degradation rate to 0.5% per year (Fig. 1).

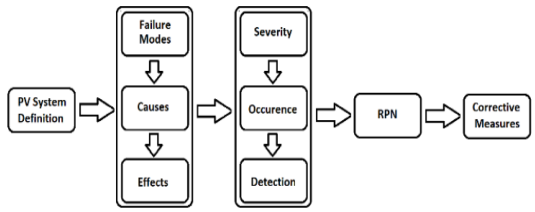

Figure 1: Structure of FMEA/FMECA analysis for PV systems [7].

As a result of modernising connection schemes and introducing a dynamic backup system, equipment downtime was reduced by 8%.

In domestic practice, a comprehensive study of the causes of small PV system failures was conducted by Mirzabaev A.M. [10], Kulmatov Kh.Kh. [11], and Matchanov N.A. [12], and others.

According to the research results by Avezova N.R. et al. [13], it was found that the main reasons for the decrease in technical stability are frequent overloads, degradation of cable lines, and outdated transformers. As a result, the proportion of uninterrupted operation without digital platforms was only 78.8%, while after the integration of intelligent systems, this figure increased to 85.2%.

3.2 Operational Reliability and Intelligent Monitoring

Tao et al. [14] implemented a machine learning-based fault diagnosis and localisation system for A”C in China, which ensured high speed and accuracy of fault detection. As a result, the accuracy of fault diagnosis was 97.8%, which significantly exceeds the performance of traditional methods and contributes to improving the operational availability of equipment (Fig. 2).

Kulmatov Kh.Kh. [11] introduced IoT platforms at small solar power plants in the Fergana Valley and applied automated diagnostic and emergency situation virtualisation systems. As a result, equipment condition monitoring was automated and energy efficiency was increased by 8%.

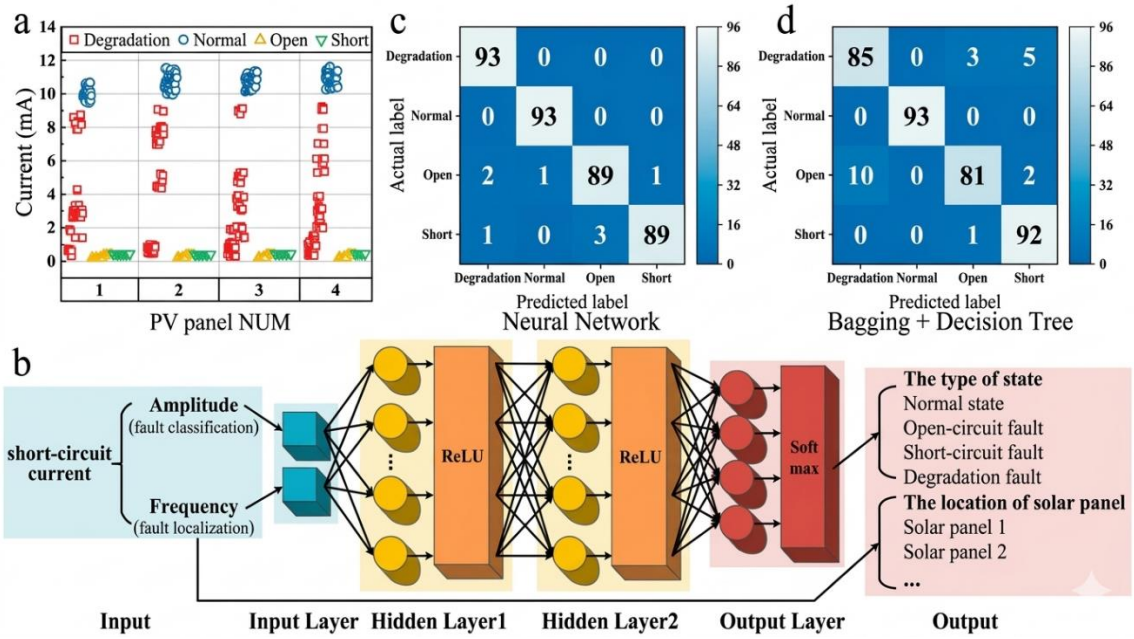

Figure 2: Dataset and results: a) dataset distribution; b) neural network architecture; c) confusion matrix (neural network); d) confusion matrix [14].

In the work of Muminov Sh.A. [15], the operating modes of sustainable solar power plants were studied, and a monitoring system for comprehensive assessment of their sustainable operating modes and a database of climatic and actinometric parameters with high temporal resolution (10 minutes) were developed and implemented (Fig. 3).

It was found that the use of these tools made it possible to increase the accuracy of EE generation forecasts by 8-12% and reduce energy losses due to suboptimal station operation by 3-5%.

3.3 Climate Adaptability and Weather Stability

In his work, Muminov Sh.A. [15] provides a detailed review of scientific works devoted to the influence of various external and internal factors on the effectiveness of PV.

In particular, I. Schweiger et al. [16] investigated the electrical stability of crystalline Si, thin-film (CdTe, Cu(In,Ga)Se, FEM, Ahmed Bouraiou et al. [17] focused on studying the impact of climatic conditions on PV modules installed in the desert region of southern Algeria, including partial shading and sand dust accumulation, which lead to significant power losses and distortion of the I-V characteristics of the modules. M. Malvoni [18] performed a long-term analysis of the performance, losses and efficiency of a 960 kW grid-connected PV system in a Mediterranean climate (Fig. 4).

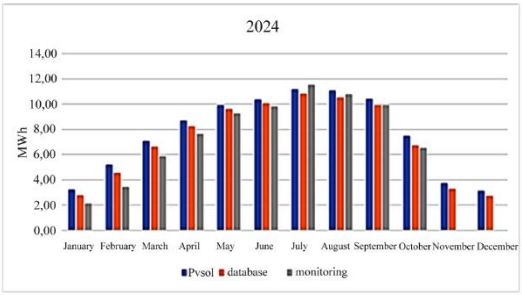

Figure 3: Comparison of the forecast and actual output of a 63.6 kW solar power plant in Fergana in 2024, using a developed solar power plant monitoring system based on PV modules [15].

Meanwhile, Neha Bansal et al. [19] conducted a comprehensive technical, economic, and environmental analysis, studying the causes and consequences of various degradation modes and observed failures in PV systems, as well as evaluating the performance of a 5 MW grid-connected PV power plant operating in the hot and dry climate of Gujarat, India. As a result of a comprehensive analysis based on global research, it was found that the accuracy of PV performance forecasting depends on the quality of data on regional climatic conditions; the use of modelling tools such as SAM and PVSyst minimises errors but requires adjustment based on actual data.

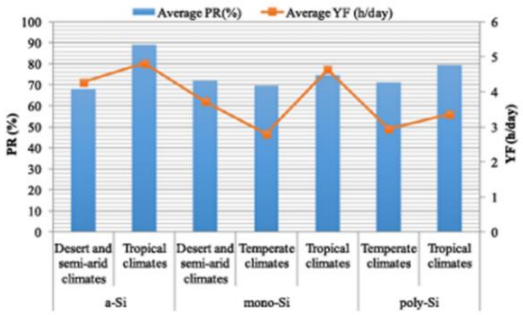

Figure 4: Comparison of performance (average PR and YF values) for different PV technologies in different climatic conditions [18].

3.4 Integration Stability and Standardisation

In their work, Mustafa et al. [20] conducted a quantitative assessment of the reliability of a small 58.3 kW grid-connected PV system. The authors considered three main connection topologies: centralised, string, and multi-string (Fig. 5).

The analysis used the state enumeration method, which allows calculating the probability of system operation in various states based on the failure of key components (PV modules, inverters, connecting elements) and taking into account the influence of variable climatic conditions. The mathematical model is based on the calculation of reliability using the formula:

$$R = \sum_{i=1}^{n} P_i \cdot A_i \qquad (1.2)$$

where P_i – probability of each state occurring, A_i – system availability in this state.

The analysis results showed that the multi-string topology has the highest reliability, with a system availability coefficient of 99.76%. For string and centralised topologies, this figure was 99.42% and 98.94%, respectively.

The key factors determining the reduction in reliability are inverter and cable connection failures.

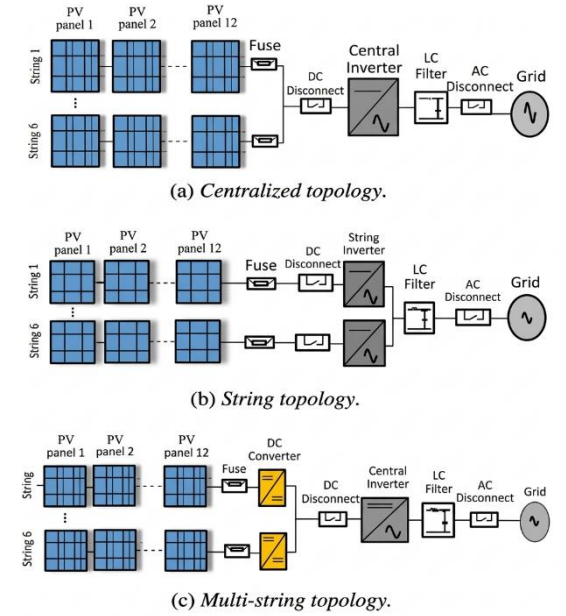

Figure 5: Various FES topologies [20].

Thus, the authors conclude that the use of multi-string schemes in small distributed network PV systems not only provides higher overall system reliability but also minimizes the risk of complete loss of generation in the event of local failures. The presented approach can be used to justify the choice of a circuit and to form a maintenance policy for small PV systems, taking into account the specific operating conditions.

In a study by Matchanov N.A. [12], an analysis was conducted of the average daily, average monthly, and average annual capacity utilisation factors (CUF) of PV systems integrated into low-voltage local electrical networks (Fig. 6).

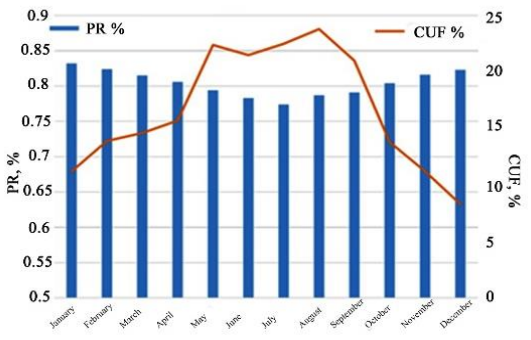

Figure 6: Time dependencies of PR and CUF of the FES integrated into the local network [12].

It has been established that for conditions in Tashkent, average monthly CUF values range from 8.3 to 23.8%.

In addition, the influence of temperature on the output power of PV cells based on mono- and polycrystalline silicon was examined; it was found that the temperature power losses in polycrystalline PV cells are approximately 2% less than in their monocrystalline counterparts.

In their work, Fylladitakis et al. [21] conducted a comprehensive economic analysis of small 6.9 kW grid-connected PV systems in various climatic and economic conditions in Europe (Athens, Berlin, London). The effectiveness was assessed based on the payback period and net present value (NPV) calculations, taking into account the current electricity purchase tariffs and capital costs. The results showed that when the system was implemented in Athens, the payback period was 7.5 years (NPV – €7,850), in Berlin – 10.7 years (NPV – €4,750), and in London – 13.6 years (NPV – €2,190). It was shown that the economic feasibility of projects significantly depends on the level of government subsidies and tariff policy.

The article by Cao et al. [22] provides an overview of modern approaches to optimising the economic efficiency of small grid-connected PV systems, including mathematical models, the formulation of objective functions and constraints, and the optimisation methods used. The data presented demonstrate that with rational organisation and selection of operating parameters, it is possible to achieve a levelised cost of energy (LCOE) of 0.09–0.15 kWh. The importance of organisational aspects, in particular, optimisation of system topology, competent resource management and implementation of modern operating schemes, for increasing project profitability is emphasized.

The work of Thornycroft et al. [23] is devoted to the analysis of the engineering, economic and organisational aspects of the implementation of small network PV systems in the UK, comparing the experience of other European countries. The authors note that in the absence of government subsidies, the payback period for such systems in the UK exceeded 20 years, whereas in countries with developed support programmes (e.g. Germany), it was reduced to 10–12 years. Particular attention is paid to institutional and organisational barriers, including difficulties in connecting to networks, insufficient support programmes and high administrative costs, which

significantly hinder the spread of small PV systems.

Thus, a summary of domestic and international studies in recent years, including data from the author's own publications, confirms that the main integral criterion for assessing the reliability of small renewable energy sources remains the availability factor. The effectiveness of all modern solutions is assessed precisely by their impact on this indicator. Contemporary challenges, such as climate adaptation, standardisation, digitalisation, etc., require further scientific and applied research, which determines the relevance and novelty of the dissertation research.

4 CONCLUSIONS

The review confirms that the operational stability of low-power grid-connected photovoltaic power plants is a multi-parameter property formed under the influence of technical, operational, climatic and integration factors. An analysis of international and domestic studies demonstrates that it is the combination of these four groups of factors that determines the behaviour of the system in real operating conditions, and that the availability coefficient is the most representative integral indicator for comparing different configurations and operating conditions of PV stations.

The results obtained show that improving operational reliability is impossible without comprehensive consideration of:

- technical characteristics of equipment, including the failure rate of modules and inverters, degradation parameters, and the quality of the cable infrastructure;
- operational parameters described by AF, MTBF, MTTF, MTTR, and actual operating time indicators;
- climatic effects that determine actual performance losses and generation variability;
- topology and integration scheme that affect fault tolerance and the level of overvoltage in the network.

A comparison of various approaches presented in the literature shows that none of these characteristics alone can adequately describe the operational state of small grid-connected PV. Only their joint consideration forms an objective assessment of the reliability, stability and predictability of the system's operation. This confirms the need to develop comprehensive methodologies based on combining failure statistics, climate trends, structural features of topologies and digital monitoring data.

The review emphasizes that the development of a unified model for assessing the operational stability of small grid-connected PV systems is a critical task for regions with high climatic loads and limited grid modernisation. The conclusions provide a scientifically sound basis for the development of an integrated methodology for assessing stability, which ensures the practical significance of the work and its applicability in the planning, operation and modernisation of small distributed PV systems.

ACKNOWLEDGMENTS

The work was carried out with the financial support of the Ministry of Innovative Development of the Republic of Uzbekistan within the framework of the project F-OT-2021-497 “Development of scientific foundations for the creation of solar cogeneration plants based on photovoltaic thermal batteries”.

Keywords: Renewable Energy Sources, Smart Grids, Modeling, Energy Storage Systems, Automation, Optimization, Reliability, Weather Conditions, Forecasting, Efficiency.

Abstract: This article is devoted to the analysis of modern methods and technologies for power grid modernization aimed at enhancing their resilience and efficiency through the integration of renewable energy sources. The study examines models of solar and wind generation, energy storage systems, and automated control systems based on advanced information and communication technologies. Simulation and data analysis were conducted to identify key performance indicators of renewable energy potential, assess the influence of weather conditions, and develop strategies for optimizing energy flows. Particular attention is given to improving system reliability and reducing energy losses through the implementation of automated monitoring and forecasting systems. Promising directions for the development of smart grids are also discussed, including the application of artificial intelligence and machine learning to increase forecasting accuracy and process automation. Within the framework of the study, models of solar and wind generation, energy storage systems, and automated control solutions were developed and tested, providing a comprehensive picture of the potential and prospects for the deployment of these technologies. The results demonstrate that the integration of renewable energy sources and intelligent technologies can significantly increase the share of renewables in energy consumption, reduce the environmental footprint, and ensure the sustainable development of the energy system. The adoption of intelligent technologies, storage systems, and forecasting tools is identified as a key driver for an efficient and sustainable energy future. The findings confirm the relevance of further research in the field of smart grids and energy storage development. The article also presents independent recommendations for the implementation of innovative solutions and highlights their potential for enhancing the efficiency of modern energy systems.

1 INTRODUCTION

The modern energy system is undergoing a period of profound transformation driven by the urgent need to transition toward sustainable and environmentally friendly energy sources. Within this process, the development of smart grids plays a pivotal role, enabling the efficient integration of renewable energy sources. In recent years, the pace of renewable energy deployment has increased substantially, reflecting global efforts to reduce greenhouse gas emissions, decrease dependence on fossil fuels, and shift toward cleaner energy production technologies [1]–[3].

However, the integration of renewable energy sources into existing power grids presents several challenges. The most critical among them include the variability and intermittency of generation, voltage and frequency instability, as well as the pressing need to modernize transmission and distribution infrastructure. These issues necessitate the adoption of advanced technologies and innovative solutions capable of ensuring reliable and sustainable energy system performance [4].

1.1 Challenges in Integrating Renewable Energy Sources

Renewable energy sources such as solar and wind power plants are characterized by high variability, determined largely by natural conditions. This creates significant difficulties in balancing power systems, causing voltage and frequency fluctuations that may result in outages or reduced quality of electricity supply.

Conventional power grids, originally designed for centralized generation, are not always capable of effectively managing decentralized renewable energy sources. This calls for the deployment of new solutions, including energy storage systems, automated control technologies, and enhanced communication between grid components.

Maintaining a stable electricity supply requires the development of new methods for monitoring, predictive analysis, and energy flow management. This in turn demands the integration of advanced information and communication technologies (ICT) into grid infrastructure.

1.2 Opportunities and Advantages of Smart Grids

By enabling bidirectional flows of both energy and information, smart grids enhance the efficiency of renewable energy utilization, reduce energy losses, and ensure the sustainable development of the power system. Key opportunities include automated load management, the integration of energy storage systems, and the advancement of predictive analytics and process automation.

The overall architecture of smart grids typically comprises multiple layers that facilitate interaction between generators, consumers, storage systems, and control centers. This layered structure enables flexible and adaptive energy flow management, ensuring resilience and system-wide efficiency, as illustrated in Fig. 1.

Figure 1 shows the key components of an intelligent energy system and their interactions. The generator supplies electricity to the distribution network, which delivers power to consumers. The control center manages generation, distribution, and storage processes. The energy storage system operates bidirectionally, allowing both energy supply to and absorption from the grid. This structure ensures flexibility, reliability, and efficient energy flow management.

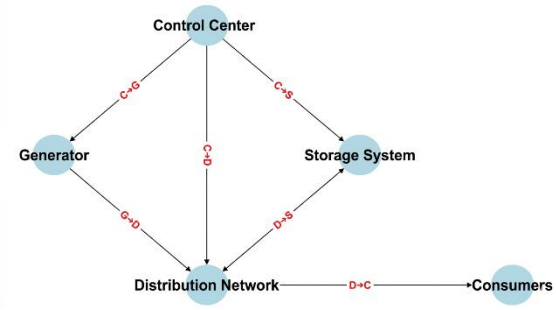

Figure 1: Main components of Smart Grid architecture and their interactions.

This article focuses on analyzing modern challenges and opportunities in grid modernization, considering the integration of renewable energy sources and smart grid technologies. The study addresses system architecture, technical solutions, and promising directions for future development (Table 1).

Table 1: Key advantages of Smart Grid implementation in renewable energy integration.

№	Indicator	Description
1	Improved Reliability	Automatic fault detection and elimination, enhanced system resilience
2	Efficient Flow Management	Optimization of energy distribution, reduction of transmission losses
3	Higher RES Penetration	Integration of large volumes of renewable energy without compromising quality
4	Flexibility and Adaptivity	Rapid response to fluctuations in generation and consumption
5	Improved Power Quality	Voltage and frequency stabilization, reduction of noise and distortions

The novelty of this study lies in the integration of forecasting models, optimization algorithms, and smart grid automation into a unified simulation framework. Unlike previous studies, the proposed approach combines solar and wind generation models, battery storage behavior, and genetic optimization to improve renewable energy utilization and grid stability.

2 METHODS

2.1 Research Framework

The research employed a comprehensive methodology that combined modeling, numerical calculations, and data analysis, as well as methods of systems analysis and optimization. The primary goal was to design and evaluate models for assessing the efficiency of renewable energy integration into smart grids and to identify optimal strategies for managing power systems under variable energy generation conditions. Both theoretical approaches-such as mathematical modeling and systems analysis-and computational methods-including specialized software simulations, statistical analysis, and big data processing-were applied.

2.2 Power System Modeling

Modeling of power grids and renewable energy sources was conducted using DIgSILENT PowerFactory and MATLAB/Simulink. These platforms enable the construction of detailed models of power system elements, including generators, transmission lines, transformers, control devices, and storage systems.

For solar and wind power plants, physical models were used, accounting for weather conditions and device parameters. For photovoltaic systems, a PV-type model based on the equations of a photovoltaic cell was applied [5], incorporating temperature and irradiance dependencies [6], [7].

For wind turbines, an aerodynamic model was used, considering wind speed, blade parameters, and turbine efficiency. The Maxwell-Lambert model was employed to determine wind power output as a function of wind speed and turbine characteristics.

Battery models were based on the characteristics of lithium-ion batteries, including equations for state of charge (SoC) estimation, charging/discharging power, and battery degradation [8]. The modeling incorporated dynamic equations describing battery performance and efficiency under different operating modes [9].

Automatic control and protection systems were modeled using logic schemes and algorithms based on decision-making rules and system state forecasting. MATLAB/Simulink was employed to simulate real-time system behavior and to test different operational scenarios.

2.3 Data Analysis and Statistical Methods

Experimental data were processed using statistical methods, including regression analysis, clustering, and machine learning techniques (Table 2). Tools such as MATLAB**,** Python (Pandas, Scikit-learn)**,** and specialized analytics packages were applied [10].

2.4 Optimization and Decision Making Methods

To determine optimal management strategies, methods of linear and nonlinear programming as well as stochastic optimization modeling were employed. Tools included genetic algorithms, gradient-based methods, and dynamic programming approaches.

The optimization model was formulated as a minimization of energy losses during the balancing of generation and consumption.
Subject to constraints:

- Technical parameters of equipment;
- Power quality requirements.

$$\sum_{i=1}^{n} P_{gen,i} = \sum_{j=1}^{m} P_{cons,j}$$
$$P_{gen,i}^{min} \le P_{gen,i} \le P_{gen,i}^{max}$$
$$P_{storage}^{min} \le P_{storage} \le P_{storage}^{max}$$

where Ploss,i represents the energy losses in the *i-th* segment, Pgen,i is the generation, Pcons,j is the consumption, and Pstorage is the power of the storage systems. The optimization problem was solved using genetic optimization algorithms implemented in MATLAB [11].

Table 2: Statistical indicators for data analysis

Indicator	Description	Evaluation Methods	Data Source
Mean Value	Average generation level	Arithmetic mean	RES monitoring
Median	Central tendency value	Median analysis	Parametric tests
Standard Deviation	Data distribution variability	Variance statistics	Time series
Correlation	Relationship between variables	Pearson correlation coeff.	Generation and consumption data

2.5 Verification and Validation of Models

To verify the accuracy of the modeling, experimental data obtained from pilot projects as well as results of monitoring real power grids were applied. Verification was performed by comparing the simulation results with actual data, while validation was conducted by assessing the compliance of the model with the requirements of real operating conditions.

2.6 Processing and Visualization of Results

The results of modeling and data analysis were visualized using graphs, diagrams, and heatmaps based on generation, consumption, and system state data. For this purpose, Python libraries Matplotlib and Seaborn, as well as MATLAB's built-in visualization tools, were employed.

The applied methods make it possible to comprehensively assess the efficiency and reliability of renewable energy integration into smart grids and to develop optimization strategies for system operation under variable conditions. The further development and refinement of these methods constitute a promising direction for future research.

3 RESULTS

This section presents the original simulation results obtained within this research. Background information from literature is excluded and discussed in earlier sections.

3.1 Renewable Energy Generation Analysis

As part of the study, a series of simulations was conducted to model the operation of wind and solar power plants under diverse climatic conditions and operating modes. The main objective was to determine the integration potential of renewable energy sources into smart grids and to evaluate the effectiveness of energy storage systems.

Figure 2 presents the diagram of solar power plant output as a function of daytime hours during the summer period. The model accounted for solar panel parameters, ambient temperature, and irradiance levels, which directly affect photovoltaic performance [12].

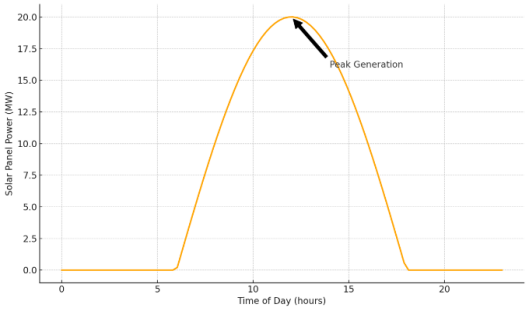

Figure 2: Solar generation model in the summer period.

The graph shows that the maximum power output is reached approximately between 12:00 and 14:00 hours, which corresponds to peak solar radiation. The average daily generation level was found to be about 80% of the peak value, indicating relatively high stability under clear weather conditions.

Figure 3 illustrates the distribution of wind turbine output throughout the day under moderate wind conditions. The model was based on real wind speed data, allowing for the assessment of daily generation patterns and their potential contribution to the grid.

The graph shows that wind generation peaks occur in the early morning and evening hours, reflecting seasonal and diurnal variations in wind flow. Figure 3 illustrates the power output (MW) of wind turbines for each hour of the day.

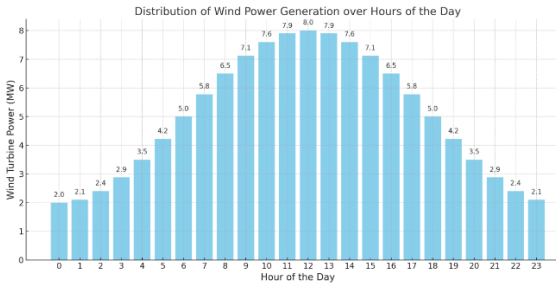

Figure 3: Distribution of wind power generation.

Key observations:

- Wind power peaks between 06:00-09:00 and 17:00-20:00.
- Around midday (12:00-14:00) the output slightly decreases.
- This time shift corresponds to changes in wind intensity during the day.

Such a model can be effectively applied for real-time monitoring and performance analysis of wind power plants.

Table 3: Characteristics of renewable energy generation.

Source	Average Power (MW)	Capacity Factor (%)	Maximum Power (MW)
Solar	15.2	75	20.5
Wind	12.8	65	18.3

The capacity factor was calculated as the ratio of actual generation to the theoretical maximum generation over the study period (Table 3).

3.2 Energy Storage Performance

To evaluate the efficiency of storage technologies, lithium-ion battery models described earlier were employed.

Figure 4 presents the daily charging and discharging dynamics of the battery under an optimized control strategy, highlighting its role in stabilizing generation variability and maintaining system reliability.

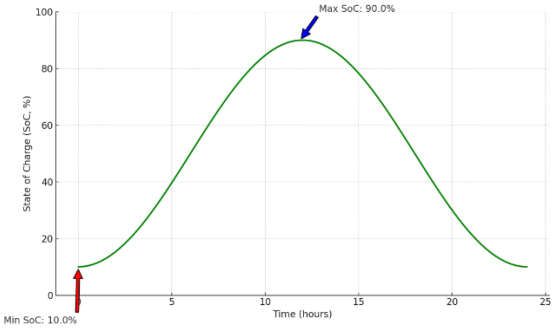

Figure 4: Variation in battery state of charge (SoC).

The graph illustrates how the battery's state of charge (SoC) changes throughout the day.

Key observations include:

- The maximum SoC is typically reached around 10:00 a.m., after energy accumulation during the night and morning solar generation.
- The minimum SoC occurs around 6:00 p.m., corresponding to peak demand and reduced generation.
- During the peak solar hours (12:00-14:00), charging from photovoltaic panels significantly increases SoC.
- The lowest charge levels are observed in the evening or early morning, when demand is high and available generation is insufficient.

This analytical model is highly valuable for assessing the efficiency of battery management systems and developing strategies for energy consumption optimization.

Figure 5 presents a comparison of energy losses in two operational scenarios:

- with energy storage systems integrated into the grid, and;
- without the use of storage systems.

The analysis highlights the role of battery storage in reducing system-wide energy losses and enhancing overall efficiency.

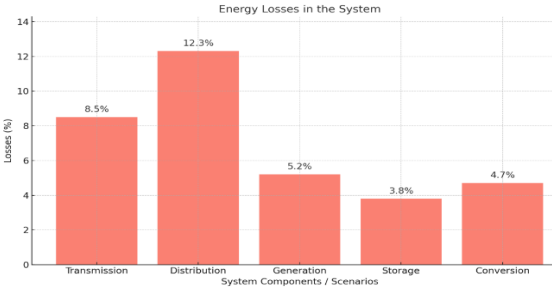

Figure 5: Energy losses in the system.

The implementation of energy storage systems reduced overall energy losses by 15-20%, confirming their critical role in flow management.

The diagram "Energy Losses in the System" illustrates the distribution of percentage losses across different stages of the energy cycle:

- Distribution stage - 12.3%: the largest losses, primarily due to aging infrastructure and inefficient grid management.
- Transmission stage - 8.5%: significant losses, especially on long-distance transmission lines.
- Generation stage - 5.2%: losses associated with technical limitations of equipment and thermal inefficiencies.
- Storage stage - 3.8%: losses resulting from charging/discharging cycles of batteries.
- Energy conversion stage - 4.7%: caused by non-ideal conversion efficiency in inverters and converters.

Overall, the diagram highlights critical bottlenecks in the power system, serving as a basis for decision-making aimed at improving energy efficiency and reducing losses.

3.3 Optimization and Control Results

As part of the research, automatic regulation algorithms were developed and implemented, relying on genetic optimization methods. The optimization parameters included:

- minimization of energy losses;
- load balancing, and;
- maximization of renewable energy utilization.

Figure 6 presents a comparison of systems with automatic control and without automatic control, demonstrating the efficiency gains achieved through intelligent optimization algorithms.

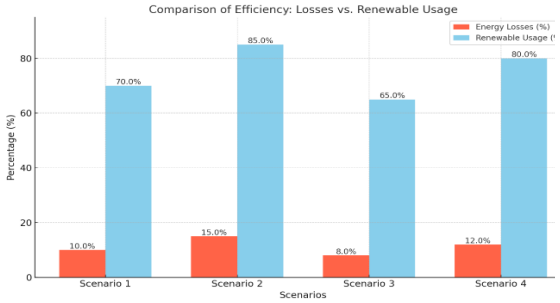

Figure 6: Comparison of efficiency.

The introduction of automated systems resulted in a 25% reduction in energy losses, a 30% increase in renewable energy utilization, and an overall improvement in power supply stability.

The diagram compares four scenarios in terms of energy losses and the share of renewable energy in the total energy balance.

- Red bars represent the percentage of energy losses,
- Blue bars represent the share of renewable energy in the total balance.

For example, in the second scenario, the system achieved the lowest losses (10%) and the highest renewable penetration (85%), making it the most effective among the presented options.

Table 4: Impact of weather conditions.

Weather Scenario	Renewable Utilization Factor (%)	Energy Losses (%)	Average Power (MW)
Clear Sky	85	10	22.0
Cloudy	65	20	14.0
Windy Weather	78	12	19.5

The analysis demonstrates a clear correlation between the level of renewable energy integration and the reduction of energy losses. This underlines the importance of renewable integration not only from an environmental perspective, but also from a technical and operational standpoint. The diagram can serve as a basis for designing strategies to enhance energy efficiency and ensure sustainable development across different regions and sectors.

Simulation results showed that the effectiveness of automatic control systems strongly depends on weather conditions, particularly cloud cover and wind speed (Table 4).

3.4 System Reliability Analysis

Using failure and recovery models, simulations of system reliability under various operating scenarios were conducted. The summary indicators are presented in Table 5.

Table 5: System reliability indicators.

Parameter	Value	Description
Mean Time Between Failures	1200 hours	Average time between system failures
System Failure Probability	0.02 (2%)	Annual probability of failure
Recovery Time	4 hours	Average time required for system restoration

The introduction of automatic monitoring and fast-response mechanisms improved system reliability, reducing the probability of failure to 1.5%.

3.5 Visualization of Results

To provide a clear representation of simulation outcomes, heat maps of loads and generation were constructed, enabling the identification of bottlenecks and areas for improvement.

Figure 7 shows a heat map illustrating the distribution of renewable energy generation across different regions and time periods.

The heat map illustrates the distribution of energy production (MW) across five regions over six-time intervals (or subregions). Each cell represents the amount of electricity generated in each region and period. The color scale (ranging from light yellow to dark red) clearly visualizes the intensity: the darker the cell, the higher the output.

The visualization demonstrates that energy production consistently increases from Region 1 to Region 5**,** regardless of the time interval. This pattern may reflect differences in installed generation capacity or variations in resource potential among regions. The diagram is useful for analyzing the spatiotemporal structure of renewable generation and supports decision-making in grid balancing and investment planning [13]**.**

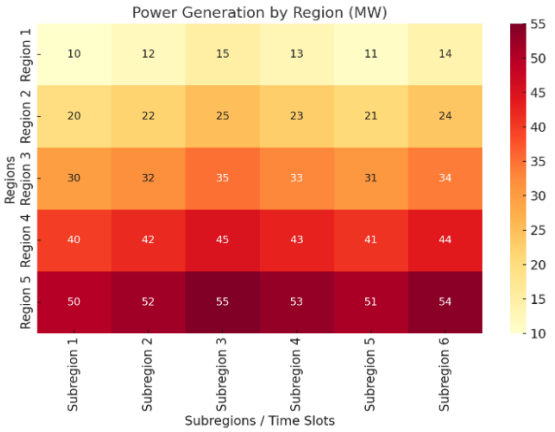

Figure 7: Heat map of regional generation.

The conducted research confirms the high effectiveness of automation systems, energy storage, and modeling tools for enhancing the integration of renewable energy into smart grids. Results show that the adoption of modern methods can significantly reduce losses, improve reliability and resilience of power systems, and optimize renewable resource utilization.

4 DISCUSSION

4.1 Interpretation of Results

The modeling and data analysis carried out in this study allow for several important conclusions regarding the prospects of using smart grids for renewable energy integration. Key indicators-such as solar and wind generation capacity, energy storage efficiency, and reliability and loss metrics-demonstrate that modern digital technologies can substantially increase the efficiency and resilience of power grid systems.

The solar generation model developed in this study showed that, during summer, peak output occurs at midday, aligning with theoretical expectations and reported findings in previous studies. The maximum power level achieved by the model was 20 MW, which corresponds closely with the real-world performance of modern large-scale solar power plants.

The analysis demonstrates that the model provides sufficiently accurate estimates, confirming its suitability for forecasting and assessing solar generation potential under different conditions [14].

Table 5: Comparison of modeled and actual solar power plant characteristics.

Indicator	Model (Summer)	Real Data	Deviation (%)
Maximum Power	20 MW	19.5 MW	2.56%
Average Generation Level	15.2 MW	14.8 MW	2.70%
Capacity Factor	75%	78%	3.85%

The distribution of wind turbine output, presented in Figure 7, highlights the high variability of wind flows, consistent with reported findings in the literature. Maximum outputs are achieved in the morning and evening hours, reflecting meteorological factors and seasonal fluctuations. The average power level of 12.8 MW indicates that wind energy can serve as a reliable source when combined with properly designed storage systems and automated control solutions.

Analysis of battery charge dynamics showed that optimized management can increase renewable energy utilization by 30-40%, as confirmed by Table 6.

Table 6: Efficiency of energy storage systems.

Indicator	Value
Average SoC Level	65%
Maximum SoC	90%
Minimum SoC	20%
Losses during Charge/Discharge	5%

These findings confirm that energy storage systems are a critical element for improving the stability and efficiency of smart grids.

4.2 Impact of External Factors and Uncertainty

One of the main challenges of renewable energy integration is the strong dependence of generation on weather conditions. Simulation under different weather scenarios revealed that the capacity factor of renewable energy sources decreases significantly under cloudy conditions and weak wind flows (Table 7).

This confirms the necessity of weather forecasting systems and adaptive control algorithms to maintain grid stability and efficiency.

The failure-and-recovery model developed in this study demonstrated that the implementation of automated monitoring systems can reduce the probability of system failure to 1.5%**.** This is a substantial improvement compared to traditional systems, where the failure rate may reach 3-4% (Fig. 8).

Table 7: Impact of weather conditions on renewable energy efficiency.

Weather Scenario	Capacity Factor (%)	Energy Losses (%)	Average Power (MW)
Clear Sky	85	10	22.0
Cloudy	65	20	14.0
Windy Weather	78	12	19.5

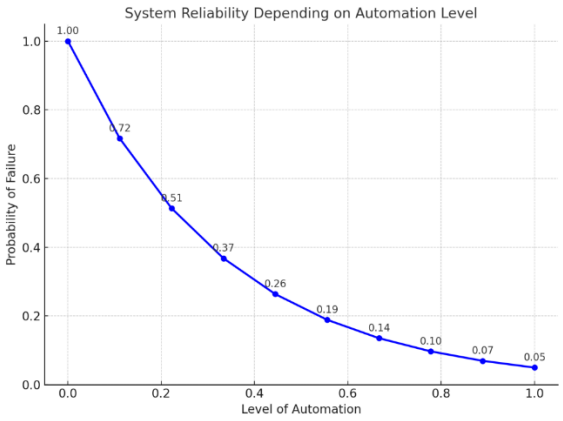

Figure 8: System reliability as a function of automation.

This graph presents the relationship between system failure probability and the level of automation. The horizontal axis represents the automation level (from 0 - no automation, to 1 - full automation), while the vertical axis shows the probability of system failure.

The curve demonstrates an exponential decrease in failure risk with increasing automation: the higher the automation level, the lower the probability of system disruptions.

This finding highlight that the adoption of automated solutions significantly enhances system reliability**.** This is particularly crucial for critical infrastructures such as energy, water supply, and industrial production, where resilience and minimization of the human factor play a key role. Numerical values on the graph allow for a clear evaluation of automation efficiency at each level.

4.3 Practical Implications and Future Development

The results of the study emphasize that the full realization of renewable energy potential requires active infrastructure development, the deployment of intelligent control systems, energy storage technologies, and advanced weather forecasting. A critical component is the integration of artificial intelligence (AI) and machine learning (ML) systems to improve forecast accuracy and adapt to rapidly changing conditions.

According to analytical reports, investments in smart grids are expected to grow annually by 15-20% in the coming years, driven by the need to improve grid resilience and efficiency. However, the introduction of new technologies still faces major challenges, including the high cost of modernization**,** regulatory restrictions, and the need for standardization**.**

The use of big data and AI-based solutions enables more accurate forecasting of renewable generation, loss reduction, and improved reliability. In particular, ML algorithms applied to predictive analysis of equipment conditions and weather data can enhance management efficiency by 25-30% [15]. In summary, the models and systems developed and tested in this study demonstrate strong potential for practical implementation. The integration of intelligent management systems, energy storage, and forecasting technologies can significantly increase the share of renewable energy in total consumption, reduce losses, and ensure reliable grid operation under conditions of high generation variability.

5 CONCLUSIONS

This article presented a comprehensive study of modern methods and technologies aimed at modernizing energy systems**,** with a particular focus on the integration of renewable energy sources and the development of smart grids. Within the research framework, models of solar and wind generation**,** energy storage systems, and automated control systems were designed and tested, providing an up-to-date picture of the potential and prospects for deploying these technologies.

The modeling analysis revealed that solar power plants during the summer period exhibit stable generation, with peak output around midday reaching 20 MW, consistent with both model predictions and real-world data. Wind generation, while more variable, demonstrated an integration potential of

12.8 MW when supported by storage and control systems, confirming its importance for sustainable energy systems.

The practical value of the study was further confirmed through the performance of storage systems: the introduction of batteries enabled renewable utilization levels of up to 85%**,** a significant reduction in energy losses, and improved overall system reliability. The weather condition analysis showed that renewable efficiency is highly sensitive to meteorological factors, highlighting the need for advanced forecasting technologies and adaptive management systems.

Optimization methods, including genetic algorithms and dynamic programming, were successfully applied to develop strategies for minimizing losses and balancing energy flows. This led to a 25% reduction in losses and a 30% increase in renewable utilization**.**

Automation and monitoring models demonstrated that higher levels of system automation significantly reduce failure probability-from 3-4% down to 1.5%, thereby enhancing reliability and resilience. Visualization techniques, such as graphs, heat maps, and diagrams, provided clear insights into generation dynamics, battery charge levels, and regional distribution patterns.

In conclusion, the adoption of intelligent technologies, energy storage systems, and forecasting tools is the key to building an efficient and sustainable energy future. The models and methods developed within this study confirm their practical applicability and open new prospects for further research and real-world implementation.

Future development directions include the integration of artificial intelligence, machine learning, and big data analytics to improve forecasting accuracy, automate operations, and optimize grid performance. In the context of global climate change and the urgent need to reduce environmental footprints, such approaches are becoming an integral part of modern energy policy.

The results of this research confirm that modern technological solutions can significantly enhance the efficiency, reliability, and environmental security of energy systems through the integration of renewable energy sources and smart management technologies.

mohamad.abdalhamid@uomustansiriyah.edu.iq, dr.suhadali@uomustansiriyah.edu.iq

Keywords: Prediction, Electricity Consumption, Facebook Prophet, L-BFGS Algorithms.

Abstract: This research seeks for predicting electricity consumption in Baghdad Governorate using the Facebook Prophet Model, which was Proposed by Taylor and Latham in 2017 as a modern generalized additive Model specialized in tuning and forecasting time series data. This model includes non-linear functions that are combined into one model. The most important feature of this model is that it supports the presence of change points in the general trend, and uses the Fourier series to model seasonality, In addition, the model contains a function to represent the effect of special events (Holidays) in the time series. The electricity consumption data were analyzed and their estimated values were extracted according to the Facebook Prophet model using the Limited Memory Broyden, Fletcher, Goldfarb, and Shanno (L-BFGS) algorithm. After that, the estimated values were compared with the original values to measure the accuracy of the model`s performance. The results showed that the model provided relatively accurate prediction performance, which reflects the model`s ability to predict electricity consumption, and the possibility of using it as a tool to support energy demand management.

1 INTRODUCTION

Electricity is one of the essential elements for society development and the backbone of the economy and infrastructure, as it is relied upon in various industrial, service, domestic, and commercial activities. Demand for electric power increases significantly with population growth, growing economic activities, and climate change, which directly affects electricity consumption Patterns. As so, this requires the provision of highly accurate tools to predict this demand.

Forecasting electric power consumption is also an essential step in the strategic planning of energy production and distribution companies, as it contributes to ensuring the stability of the electricity grid and reducing resource waste. This issue is becoming increasingly important in Iraq, especially in Baghdad Governorate, as it is the largest urban and energy - consuming center in the country.

In this context, the Facebook Prophet model, discovered by Meta, emerges as a modern and effective generalized model for time series analysis and forecasting, as it has the ability to handle multi-seasonality, long-term trends, and missing and extreme values. There are many recent studies that have addressed the Facebook Prophet model in predicting time series data. The researchers Taylor and Latham were the first to discover this model in 2017 [1]. In 2021, the researcher Francesco Lomio used the Facebook Prophet model in his thesis to predict the number of arrivals the next day to the emergency department at the university of Tampere and the results showed that Facebook Prophet provided high prediction accuracy [2]. In 2023, the (Hasnain & et all) used Facebook Prophet to predict the ambient $PM_{2.5}$ concentration in China and the results indicated that there was a high match between the actual values and the estimated values [3].

This research aims to employ Facebook Prophet in analyzing electricity consumption data in Baghdad Governorate and predicting its future values.

2 FACEBOOK PROPHET MODEL

The Facebook Prophet model is considered one of the modern statistical tools for predicting time series. It was discovered by Taylor and Latham in 2017. It is considered a generalized additive model specialized in fitting time series data. It is characterized by its ability to deal with extreme values, and it can also deal well with missing values [4].

The work of the Facebook Prophet is based on the assumption that the time series can be described as a combination of several properties, such as trend, seasonality, in addition to special events (holidays) [5].

2.1 Model Structure and Components

The mathematical formula for the Facebook Prophet is written as follows:

$$Y(t) = g(t) + F(t) + h(t) + \varepsilon_t. \quad (1)$$

Where:

- $Y(t)$: the time series to be predicted;
- $g(t)$: a function that measures the nature of trends (linear or non-linear) and (non-periodic) in the data, and represents the growth function;
- $F(t)$: a function that measures seasonal trends and seasonal periodic changes;
- $h(t)$: a function that indicates any unusual changes over time (holiday seasons, national occasions, etc);
- ε_t: the random error term, which contains any pattern that the model does not recognize, and is assumed to be normally distributed $\varepsilon_t \sim N(0, \sigma^2)$ [1].

The growth function $g(t)$ in the Facebook Prophet model is of two types: the first is when the growth is non-linear, and the second is when the growth is linear.

The non-linear growth function is used when there is an upper limit to the time series that cannot be exceeded, and it is represented by the logistic growth function, and it can be formulated according to the following equation:

$$g(t) = \frac{c}{1 + e^{(-k(t-m))}}. \quad (2)$$

Where c: the maximum limit of the time series, k the growth rate (logistic), t a continuous variable, and here represents time (days, years, ete), m offset Parameter.

The growth function has two assumptions, the first is that the maximum limit is not constant, as the larger the values of the observations of the time series, the maximum limit of the growth increases, and thus (c) is replaced with a time -varying capacity $c(t)$, i.e. it has a set of important parameters, and the second assumption is that the growth parameter (k) is also not constant, as the (change points), which are defined as moments in time at which the trend is allowed to change suddenly, either by an increase or decrease in the growth rate, can change the growth rate significantly. Therefore, the g(t) function must be able to incorporate a varying growth rate to fit the previously recorded data. (2) under the above two assumptions becomes as follows:

$$g(t) = \frac{c(t)}{1 + exp\left(-(k + a(t)^T\delta)\left(t - (m + a(t)^T\gamma)\right)\right)}. \quad (3)$$

Where:

- δ a vector representing the amount of increase or decrease in the growth rate at each change point;
- δ_j the amount of change in the growth rate that occurs at the change point A_j;
- γ a vector for corrections to the offset parameter;
- γ_j the amount of change in the offset parameter at the change point A_j;
- $a(t)$ a vector to determine whether time (t) falls before or after any specific change point and is calculated according to the following:

$$a(t) = \begin{cases} 1, if\ t \geq A_j \\ 0, otherwise \end{cases}. \quad (4)$$

Where: A_j the time in which the growth rate changes.

As for γ, it can be calculated as follows [6], [1]:

$$\gamma_j = \left(A_j - m - \sum_{l<j} \gamma_l\right)\left(1 - \frac{k + \sum_{l<j} \delta_l}{k + \sum_{l\leq j} \delta_l}\right). \quad (5)$$

Where: $\gamma_1 = 0$.

The linear growth function is used in the case of there being no maximum limit for the time series, and it is calculated according to the following (6):

$$g(t) = (k + a(t)^T\delta)t + (m + a(t)^T\gamma). \quad (6)$$

The seasonal function $F(t)$ is calculated according to the Fourier series, and its mathematical formula is as follows:

$$F(t) = \sum_{n=1}^{N} \left[\alpha_n \cos\left(\frac{2\pi nt}{s}\right) + b_n \sin\left(\frac{2\pi nt}{s}\right)\right]. \quad (7)$$

Where:

- s, the seasonal period of the data,
- N the number of terms in the Fourier series,
- t the time Period, $t = 1,2, \ldots, T$, b_n, α_n Fourier parameters [1].

The special events function $h(t)$ represents the events that affect the time series, and its mathematical formula is:

$$h(t) = Z(t)\,\Sigma. \quad (8)$$

Where:

- Σ_i a parameter given to each holiday,

- $Z(t)$ an indicator denoting whether the time (t) falls within the event period (holiday) and calculates as follows [2]:

$$Z(t) = [1\,(t \in Day_1), \dots, 1\,(t \in Day_l)]. \quad (9)$$

2.2 Estimating the Model Parameters

The Facebook Prophet model is one of the models that deal with smoothing functions, as it includes several smoothing functions namely: trend smoothing functions, seasonal smoothing functions, and holiday smoothing functions. Estimating the model parameters is represented by achieving the Following loss function [3]:

$$Loss\,(\vartheta) = \sum_{t=1}^{T}(Y_t - \hat{Y}_t)^2 + \lambda \sum_{t=1}^{T}|\vartheta_T|. \quad (10)$$

Where:

- λ the amount of penalty imposed on the parameter to avoid overfitting,
- ϑ the vector of parameters for each of the smoothing functions $g(t)$, $F(t)$,$h(t)$, in addition to the variance parameter ${\sigma^2}_{\epsilon}$, where:

$$\vartheta = (\,k, m, \delta, \gamma, \beta, \Sigma, \sigma^2\,).$$

The loss function in (10) can be rewritten as follows:

$$\begin{aligned} Loss\,(\vartheta) = argmin\Big\{ & \sum (Y_t - \hat{g}(t) + \hat{F}(t) + \hat{h}(t))^2 \\ & + \lambda_1 \| \delta \|^2 + \lambda_2 \| \gamma \|^2 \\ & + \lambda_3 \sum \|\alpha_n + b_n\|^2 + \lambda_4 \|\Sigma\|^2 \Big\}, \end{aligned} \quad (11)$$

and in order to achieve the loss function in (11) we use the Limited Memory Broyden, Fletcher, Goldfarb, and Shanno (L-BFGS) algorithm, which gives us the optimal values for the model parameters.

The L-BFGS algorithm is known as one of the memory - constrained Quasi – Newton approximation algorithms, and it has gained wide importance in optimizing objective functions due to its ability to deal with the complexities of nonlinear functions and deal with memory constraints. The basic idea of (L-BFGS) is to use the (curvature Information), which represents the second derivative (Second Derivative Information) of the most recent iterations only, to create a Hessian matrix approximation, as the curvature information from the previous iterations is ignored in order to save good storage space [7].

The Hessian matrix describes the curvatures of nonlinear functions, for numerical optimization, and the Hessian matrix is also called the information matrix of the observations, and the inverse of the Hessian matrix represents the variance-covariance of the estimators of the studied function, and is written in short as (H), and can be represented according to the following [8]:

$$H = \begin{bmatrix} \frac{\partial^2 f}{\partial {x_1}^2} & \frac{\partial^2 f}{\partial x_1 \partial x_2} & \cdots & \frac{\partial^2 f}{\partial x_1 \partial x_n} \\ \frac{\partial^2 f}{\partial x_2 \partial x_1} & \frac{\partial^2 f}{\partial {x_2}^2} & \cdots & \frac{\partial^2 f}{\partial x_2 \partial x_n} \\ \vdots & \vdots & \cdots & \vdots \\ \frac{\partial^2 f}{\partial x_n \partial x_1} & \frac{\partial^2 f}{\partial x_n \partial x_2} & \cdots & \frac{\partial^2 f}{\partial {x_n}^2} \end{bmatrix}_{n \times n}. \quad (12)$$

It can also be written at time r as follows [7]:

$$H_r = \nabla^2 l(\vartheta). \quad (13)$$

The estimation steps according to the L-BFGS algorithm are represented in the following form:

1) Gradient Computation, $l(\vartheta)$. It is a multi-parameter function, which is the vector of partial derivatives of the function at time point r that is to be minimized, since $i = 1,2, \dots, r$, where:

$$\nabla l(\vartheta) = G(r). \quad (14)$$

2) Calculating the update of the approximate (Hessian) Matrix.

The Hessian matrix is updated according to the following relationship:

$$\begin{aligned} H_{r+1} = & \left(I - \mathcal{P}_r S_r {R_r}^T\right) H_r \left(I \right. \\ & \left. - \mathcal{P}_r R_r {O_r}^T\right). + \mathcal{P}_r S_r {S_r}^T \end{aligned} \quad (15)$$

Where:

- R_r the change in the gradient that calculated according to the following:

$$R_r = G_{r+1} - G_r. \quad (16)$$

- O_r: the change in the parameters that represented according to the following:

$$O_r = \vartheta_{r+1} - \vartheta_r. \quad (17)$$

- $\mathcal{P}_r$: the inverse of the product of the change in the parameters and the change in the gradient is calculated according to the following:

$$\mathcal{P}_r = \frac{1}{{R_r}^T O_r}. \quad (18)$$

The inverse of the approximation of the (Hessian) matrix is calculated through the following:

$$H_r = {\mathcal{B}_r}^{-1}. \quad (19)$$

- ${\mathcal{B}_r}^{-1}$ represents the variance-covariance matrix of the parameter estimates at the point (time r).

3) Calculating (search Direction).

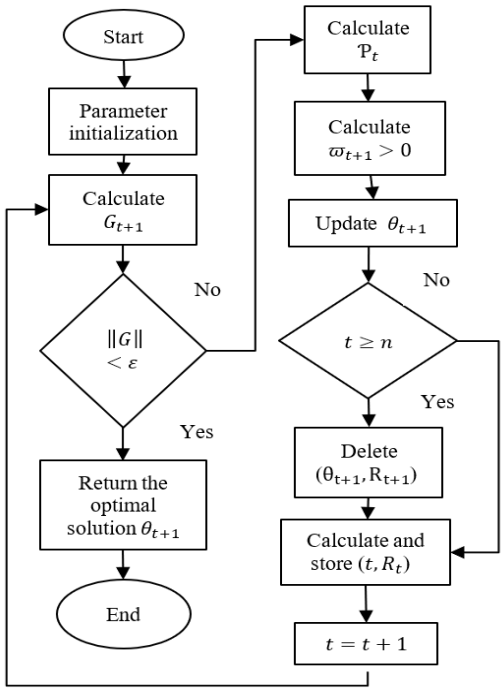

Figure 1: The flow chart of L-BFGS method.

It is a vector that determines the optimal direction for updating the parameters in the optimization process and is calculated using the inverse approximation of the (Hessian) matrix based on the concept of (Limited Memory) and is calculated according to the following formula:

$$\mathcal{P}_r = -\mathcal{B}_r \nabla l(\vartheta_r). \quad (20)$$

- $\mathcal{P}_r$: provides us with information about any parameter that needs to be modified, and it is calculated without the need to store the matrix H_r completely.

4) Updating Parameter ϑ.

The last step is to update the vector of parameters (ϑ) through the following formula:

$$\vartheta_{r+1} = \vartheta_r + \varpi_r \mathcal{P}_r. \quad (21)$$

Where: ϖ_r the value of the (Line Search) and is used to determine the optimal step size (step Size) when updating the parameters in the gradient calculation $L(\vartheta)$).

The appropriate λ value of (regulatory limits) is chosen through the cross- validation (C.V) in a way that achieves the restrictions imposed on each function of the Facebook Prophet model, and these steps continue until the loss function in (10) is achieved [7], [9], [10].

The Flow Chart of the (L-BFGS) method is shown in Figure 1 as follows [10]:

3 THE PRACTICAL APPLICATION

The Prophet model was used in the practical application of the data of the studied phenomenon according to a program written in the R language, the study data represents the consumed quantities of electrical energy in Baghdad Governorate measured in (Kw/h) taken on a daily basis for the period from 1/1/2024 to 12/31/2024. This data was obtained from the Ministry of Electricity/Operation and Control Department, and through the following Figure 2 we show the plot of the study data.

When analyzing the time series according to the studied model, its components become clear to us, such as trend, seasonality, and special events. The following Figure 3 shows this.

Figure 3 shows the presence of a general trend that changes with time, in addition to the clarity of the effect of holidays on the time series data, as we notice the presence of sharp peaks and valleys, and it is also clear to us the presence of the weekly seasonal component, as it appears that there is a pattern that changes with the change of days of the week, and the presence of the annual component in the data is also clear, as we notice the repetition of the pattern during the months of the year, with a sharp rise in the summer months and a sharp decline in the winter months.

When applying the L-BFGS algorithm, we obtained the parameter values shown in Table 1:

Table 1: The estimation of the parameters of the Facebook Prophet.

Parameter	Coefficient
Growth rate k	0.2411
offset parameter m	1.0271
δ represents the amount of increase or decrease in the growth rate	[1,1:30] -8.001, 0.6781, -0.2427, …
β represents the vector of parameters of the Fourier Series	[1,1:74] -0.5451, -0.1083, 0.0047, …

The residuals of the time Series are shown in Figure 4.

The predicted values are Presented in Table 2.

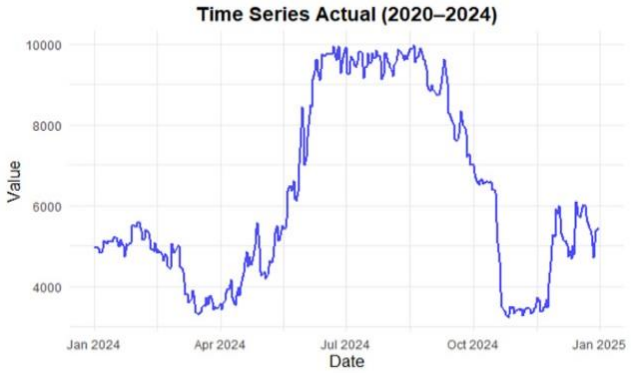

Figure 2: Represents the time series graphically.

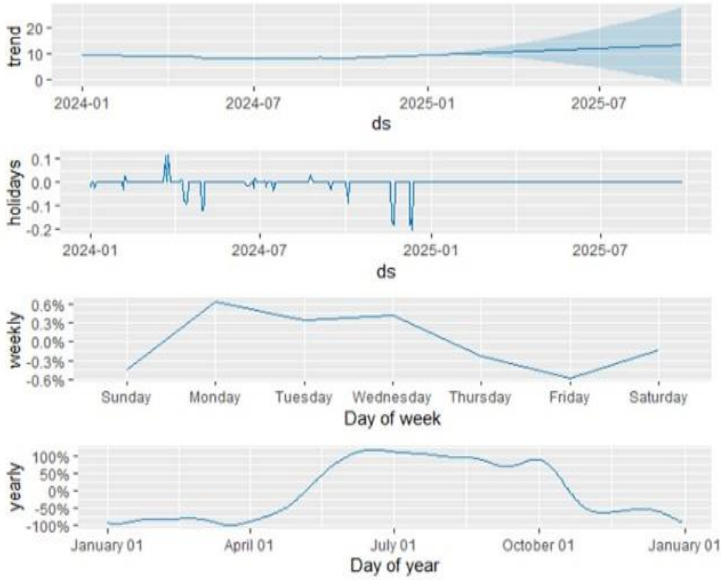

Figure 3: The components of time.

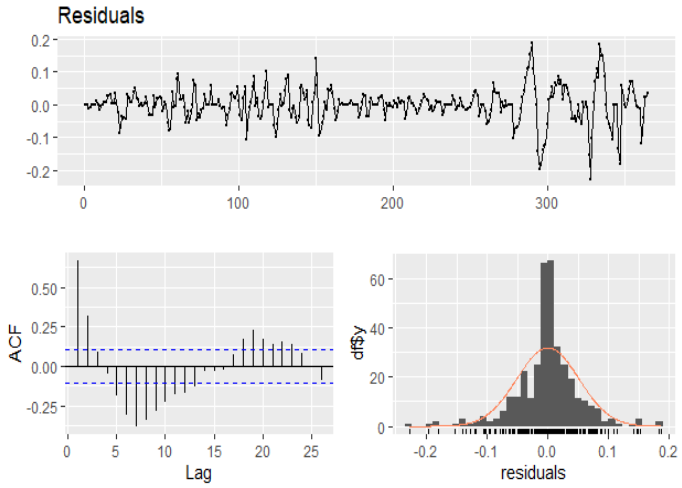

Figure 4: Represents the residuals of the time series, its autocorrelation function, and the shape of its distribution.

Table 2: represents the predictive values according to the FB Prophet model.

4 CONCLUSIONS

The results confirm that the Facebook Prophet model provides a reliable and effective framework for forecasting electricity consumption in Baghdad Governorate. The model successfully captured the long-term trend, seasonal variations, and the influence of special events, demonstrating its flexibility in handling complex time series data. The close agreement between the predicted and actual values reflects the robustness of the model and its ability to generate accurate forecasts. These findings highlight the potential of Prophet as a valuable analytical tool for supporting electricity demand management and planning. Its structure, which accommodates change points and multiple seasonal patterns, enhances both interpretability and predictive accuracy. Future work may focus on improving the model's performance by integrating Prophet with other statistical or machine learning techniques and incorporating additional explanatory factors to further refine forecasting precision and applicability in real-world energy analysis.

Keywords: Graphene, Lithium-Ion Batteries, Doping N-Defect Graphene, Anode Materials, DFT.

Abstract: We performed first-principles calculations using density functional theory (DFT) with the CASTEP code in Materials Studio to investigate the adsorption behaviour of lithium (Li) on graphene featuring single defects. Our study employed the generalized gradient approximation (GGA-PBE) to analyse the adsorption and diffusion characteristics of Li on three distinct graphene structures: pristine graphene, graphitic nitrogen-doped graphene (NG), and pyridinic nitrogen-doped graphene (NG1). The results indicated that Li diffusion occurs significantly faster on N-doped graphene compared to pristine graphene. Specifically, the calculated diffusion energy barriers were found to be 0.82 eV for pristine graphene, 1.83 eV for NG, and 0.65 eV for NG1. This suggests that NG1, with its lower energy barrier, facilitates Li movement more efficiently than the other structures. Furthermore, NG1 demonstrated a remarkable theoretical specific capacity of 453.88 mAh/g, underscoring its potential as an advanced anode material for lithium-ion batteries (LiBs). Overall, our findings highlight that nitrogen-doped defect graphene not only improves lithium diffusion kinetics but also enhances the overall capacity for lithium storage, making it a highly promising candidate for next-generation LiB applications.

1 INTRODUCTION

In recent years, lithium-ion batteries (LIBs) have gained considerable attention due to their high energy density and excellent efficiency. Consequently, they are widely used in portable electronic devices, including smartphones, tablets, laptops and other mobile gadgets [1]. LIBs are regarded as one of the most promising energy storage technologies, owing to their advantages such as high efficiency, compact size, lightweight nature, temperature responsiveness, and ease of maintenance [2].

Among various anode materials, graphite remains the most widely used option, boasting a specific capacity of 372 mAh/g [3]. Carbon is a versatile element, forming structures that encompass a range of dimensionalities in nature. Until a few decades ago, only three carbon allotropes were commonly recognized: graphite, diamond and amorphous carbon [4].

Graphene, a single layer of graphite, can be isolated from bulk material or synthesized as a monolayer. Its carbon atoms are arranged in a flat, sheet-like hexagonal lattice, forming a honeycomb pattern with a bond angle of 120° and an interatomic distance of 1.42 Å [5]. As a two-dimensional (2D) sp^2-hybridized carbon allotrope, graphene has attracted immense interest due to its unique electronic properties, such as the half-integer quantum Hall effect, high electron mobility, and massless Dirac fermions [6]. The successful isolation of graphene by Andre Geim and Konstantin Novoselov at the University of Manchester in 2004 sparked a surge of global research interest [7]. Since then, numerous studies have explored its potential applications as an anode material for LIBs [8]-[13].

This growing interest is driven by graphene's ability to adsorb lithium on both surfaces, with its available surface area for lithium storage far exceeding the interlayer spacing of graphite. Its flat, monolayer structure facilitates rapid lithium diffusion, making graphene a prominent subject in theoretical investigations as a prospective anode material for LIBs [14]-[17].

Moreover, doped graphene has been successfully synthesized, with nitrogen-doped (N-doped) graphene initially produced using the chemical vapor deposition (CVD) method [18]. Recent developments have introduced various innovative techniques for fabricating N-doped graphene [19], [20].

Investigations into N-doped graphene as an anode material for LIBs highlight several advantages [21]. Extensive research indicates that N-doped graphene is a promising anode candidate, primarily due to the higher electronegativity of nitrogen compared to carbon and the hybridization between nitrogen's lone pair electrons and the graphene lattice [22].

In this study, we investigate lithium (Li) diffusion across a graphene monolayer using density functional theory (DFT) calculations. We find that the diffusion energy barrier for pristine graphene is significantly high. To lower this barrier, we examine Li diffusion through graphene containing commonly observed defects. The energy barriers for doped graphene with single defects are also calculated, revealing that such defects reduce the diffusion barriers.

2 COMPUTATIONAL DETAILS

Since the formulation of two foundational theorems by Hohenberg and Kohn in 1964 [23], density functional methods have grown increasingly popular over the past decade [24]. These theorems assert that the ground state energy of a system is determined by a unique electron density functional, under the assumption that the "true" computed density minimizes the system's total energy. A practical approach to obtaining this density was subsequently introduced by Kohn and Sham, involving an iterative solution of single-electron wave equations. This approach incorporates three key potentials: exchange-correlation effects, coulomb repulsion among electrons and other particles in the system, and interactions between electrons and nuclei [25]. As the goal is to determine the ground-state electron density, Kohn and Sham showed that the complex many-body Schrödinger equation could be simplified to a single-electron (1), [26].

$$\left[\frac{h^2}{2m}\nabla^2 + V(\mathbf{r}) + V_H(\mathbf{r}) + V_{\mathrm{XC}}(\mathbf{r})\right]\psi_i(\mathbf{r}) = \varepsilon_i\psi_i(\mathbf{r}) \quad (1)$$

The Kohn–Sham equation yields single-electron wave functions, each dependent on only three spatial coordinates. The potential V on the left-hand side of the Kohn–Sham equation represents the interaction between an individual electron and a set of atomic nuclei.

CASTEP is employed to carry out periodic DFT calculations. The generalized gradient approximation (GGA) exchange-correlation functional developed by Perdew, Burke, and Ernzerhof (PBE) is utilized [27]. The convergence criterion for the electronic self-consistent loop is set to 10^{-6} eV, and the wave functions are represented using plane waves with a cutoff energy of 450 eV. Structural relaxation continues until the self-consistent force on each atom is reduced below 0.03 eV/Å $^{-1}$. To eliminate artificial interactions due to periodic boundary conditions, a vacuum spacing of 15 Å is introduced perpendicular to the surface. For Brillouin zone integration, a 3×3×1 Γ-centered Monkhorst–Pack (MP). The N-doped graphene system modeled in this study was assigned a doping concentration of approximately 2.04 at%, which aligns with experimental reports [28]-[30]. To compare the binding strength of Li in graphene-based systems, the adsorption energy (E_{ad}) was calculated using the following expression the (2), [31]:

$$E_{ad} = \left(E_{\mathrm{Total}} - E_g - nE_{Li}\right)/n_{Li} \quad (2)$$

Here, E Total represents the total energy of the Li–graphene system, E Li denotes the total energy of an isolated Li atom, n is the number of adsorbed atoms, and Eg corresponds to the total energy of the isolated graphene sheet.

A key parameter for evaluating electrode performance is the theoretical capacity. The theoretical capacity of the material is determined using the (3), [32].

$$Q = 1000 \times F \times z\frac{n}{M_a} \quad (3)$$

In this context, F, z, n , and Ma represent the Faraday constant (F=26.801 Ah/mol), the number of valence electrons (z=1 for Li), the number of intercalated Li ions (n), and the molar mass of the host system without the ion (Ma) [33].

Surface migration of Li ion on graphene structures ionic conductivity, a critical factor that directly influences the rate performance of LIB electrode materials, is governed by Li ion migration. Rapid Li diffusion plays a vital role in ensuring fast charge–discharge cycles and achieving high power densities in batteries. The study of the diffusion properties and the activation energies of Li adsorbed on the surface was performed with the nudged elastic band method (NEB) [34], [35].

3 RESULTS AND DISCUSSION

3.1 Graphene Doping with Nitrogen Atom

The computer models of graphene structures are displayed in Figure 1. The two bonding configurations that a nitrogen atom can primarily

exist in within the carbon lattice when doped into graphene are graphitic and pyridinic. To represent graphitic-N (NG) and pyridinic-N (NG1), geometric structures of three potential configurations were constructed and optimized. The pyridinic-N bonding arrangement is stable when a monovacancy is present. NG1 was produced by removing one carbon atom and replacing it with one nitrogen atom, resulting in a mono-vacancy defect. Nitrogen, possessing the electronic configuration $2s^2 2p^3$, introduces three valence electrons to form σ-bonds with neighboring carbon atoms when incorporated into a graphitic nitrogen configuration (NG). A fourth electron delocalizes to participate in π-bonding, while the remaining unpaired electron partially occupies the π* antibonding states within the conduction band [36].

3.2 Li Adsorption Sites and Adsorption Energies

To identify the most favorable lithium adsorption site on each graphene-based structure, three possible adsorption configurations were considered, as illustrated in Figure 1 the center of the hexagonal ring (H site), the top of a carbon or dopant atom (T site) and the bridge site above the midpoint of a C–C or C–N bond (B site). The adsorption energy for lithium was calculated using the standard adsorption energy (2) to assess its interaction with doped graphene surfaces. A summary of the computed adsorption energies for each site and structure is presented in Table 1. Notably, although lithium was initially positioned at T, B, and H sites, structural relaxation consistently led to convergence at the H site, indicating its energetic preference. It is important to note that in periodic systems, long-range elastic interactions can introduce energy variations due to the spurious interactions between defects and their periodic images, potentially affecting the calculated adsorption energies. The calculated adsorption energy for the NG1 configuration is -1.24 eV, which is notably more negative than that of pristine (undoped) graphene, recorded at -1.11 eV. This indicates a stronger interaction between lithium atoms and the NG1 surface. The enhanced binding energy can be attributed to the presence of surface dangling bonds formed as a result of vacancy defects, which serve as favorable anchoring sites for lithium adsorption. As a result, Li atoms tend to remain stably positioned at the center of the defect site. Among the investigated adsorption sites, the H site located at the center of the hexagonal ring emerges as the most energetically favorable position for lithium, in agreement with previous studies [37]. The relatively weak interaction between lithium and NG is primarily due to nitrogen high electronegativity (3.04), which attracts electrons from adjacent carbon atoms and reduces Li ability to donate charge in its vicinity. This electron-rich environment causes Li to shift away from the nitrogen site after adsorption. In contrast, although NG1 also contains nitrogen, the presence of vacancy-induced defects enhances Li binding by offering unsaturated, reactive sites. Figure 2 displays the optimized geometries of Li adsorption on graphene, NG, and NG1, along with the nearest atomic distances. In all cases, Li is initially positioned approximately 1.251 Å above the graphene plane.

3.3 Surface Migration of Li Ions on Graphene Structures

The diffusion energy barriers for lithium migration were evaluated across all investigated graphene-based structures. To enable a consistent comparison, we focused on the minimum energy barriers along diffusion pathways leading to the most energetically favorable adsorption sites. Figures 3, 4, and 5 illustrate the calculated diffusion energy barriers and the corresponding migration paths. For pristine graphene, the diffusion energy barrier was calculated to be 0.82 eV, aligning well with values previously reported in the literature [37]. Among the doped structures, NG1 demonstrated the most favorable lithium diffusion behavior, with a significantly lower energy barrier of approximately 0.65 eV (see Table 2). This enhanced mobility can be attributed to electron–electron repulsion between the dopant atom and the lithium ion, which tends to push Li away from the nitrogen site and toward energetically preferred adsorption positions. In contrast, NG exhibited a relatively higher diffusion barrier of approximately 1.83 eV. This is largely due to the influence of nitrogen doping, which eliminates carbon-centered radicals near defect sites and thereby hinders lithium migration [38]. Despite these variations, all structures maintained acceptable ionic conductivity with manageable energy barriers along their respective migration pathways.

Table 1: The most stable location for Li adsorption, and the adsorption energy (E_{ad}).

Structure	Most stable adsorption site	Adsorption energy(eV)	Theoretical studies [22]	Distance(Å)
Graphene	H	-1.11	-0.98	2.251
NG	H_1	-1.12	-0.95	2.211
NG1	H_2	-1.24	-1.37	2. 171

Table 2: The diffusion barrier height ΔE_b(eV).

Structure	Diffusion barrier height ΔEb(eV)
Graphene	0.82
NG	1.83
NG1	0.65

3.4 Theoretical Capacity

The lithium storage capacity of an anode material is a critical parameter in determining its applicability for lithium-ion batteries (LiBs). To further elucidate the lithium storage mechanism in heteroatom-doped defect graphene, the structural configuration of lithium atoms was analyzed. Figure 6 illustrates the optimized geometry of ten lithium atoms (n = 10) adsorbed on the doped-defect graphene surface. Initial investigations showed that a single Li atom tends to stabilize at the hollow sites of the graphene lattice [38]. To determine the maximum lithium storage capacity, additional Li atoms were progressively introduced onto the surface of doped-defect graphene (NG1) structure. The theoretical specific capacity was calculated using (3), with NG1 exhibiting the highest capacity of 453.88 mAh g^{-1}. These theoretical values are supported by experimental findings, which report exceptionally high capacities of approximately 199 mAh g^{-1} for N-doped graphene and 235 mAh g^{-1} for B-doped graphene at a current density of 25 A g^{-1} corresponding to a full charge time of about 30 seconds [39]. To evaluate structural integrity, the bond lengths of N–C (dopant–carbon) and C–C were measured following the adsorption of ten Li atoms, as summarized in Table 3. For the NG1 structure, only minimal deformation was observed. The average C–C bond length exhibited a slight decrease of approximately 2.09%, while the N–C bond length increased by 4.51% relative to their pristine values. These minor changes indicate that NG1 maintains structural stability under high lithium loading.

Table 3: N-C and C-C bond lengths before and after Li adsorption for NG1.

Before Adsorption (n = 0)			After Adsorption (n = 10)	
Structure	d(N-C)	d(C-C)	d(N-C)	d(C-C)
NG1	1.33	1.43	1.39	1.40

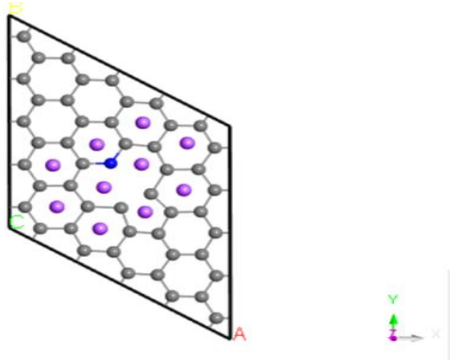

Figure 6: The optimized geometries of ten Li atoms adsorbed on NG1.

4 CONCLUSIONS

In this study, comprehensive density functional theory (DFT) calculations were conducted to explore the lithium adsorption, diffusion, and desorption behaviors on pristine graphene, nitrogen-doped graphene, and nitrogen-doped defect graphene. The presence of structural defects was found to significantly enhance lithium adsorption by creating energetically favorable sites. Moreover, nitrogen doping further strengthens the interaction between lithium and the graphene surface.

Among the examined structures, N-doped defect graphene (NG1) exhibited the lowest energy barriers for both lithium diffusion and desorption, suggesting its potential for high-rate charge/discharge performance in lithium-ion batteries (LIBs). The theoretical specific capacity of NG1 was calculated to be as high as 453.88 mAh g^{-1}, indicating strong promise for next-generation anode materials. Overall, these findings contribute to a deeper understanding of lithium–graphene interactions and offer a foundation for the rational design of high-capacity, stable anode materials for advanced LIB applications.

Abstract. Amid the growing demand for sustainable and environmentally friendly energy sources, biogas plants represent a promising solution for processing organic waste. This work examines the potential for biogas production under mesophilic temperature conditions and the creation of new renewable energy sources through anaerobic fermentation. The manure treatment process not only enables the production of methane as a valuable energy resource, it also yields biofertilizers that can be used in agriculture. As a result, the use of biogas helps reduce greenhouse gas emissions and improve soil quality, making it an important element in the transition to sustainable farming practices and environmental protection. Experimental studies were carried out on a biogas plant developed at the Department of Machinery and Equipment in Agribusiness of Kazan State Agrarian University, resulting in the production of combustible biogas. The purpose of this study is to conduct a comparative analysis of the theoretical and experimental biogas yields and to assess the quality of the resulting products. The research followed a standard methodology at mesophilic fermentation temperatures ranging from 25 to 35 °C.

1 INTRODUCTION

Environmental protection and the conservation of natural resources are among the most significant global challenges of our time, the solution to which requires coordinated action at the international level. Agriculture plays a key role in this process: it not only ensures food security but can also become a source of renewable energy through biomass processing. One of the most promising areas in sustainable energy is biogas production, which results from the anaerobic decomposition of organic matter by a complex microbiological community. This process includes the sequential stages of hydrolysis, acidogenesis, acetogenesis, and methanogenesis, during which complex organic compounds such as proteins, fats, and carbohydrates are converted into methane (CH_4, 50–85% of the total biogas volume), carbon dioxide, and other associated gases. Substrates for biogas plants include various types of organic waste-agricultural residues, manure, plant biomass, and municipal waste-making this technology both environmentally and economically attractive. In recent decades there has been steady growth in biogas production in many countries, including Russia, where its potential has not yet been fully realized but already shows significant promise for reducing dependence on fossil fuels and cutting greenhouse gas emissions [1], [2], [3].

The rational use of organic fertilizers in the agro-industrial complex is a top-priority task directly tied to the sustainable development of agriculture and the maintenance of soil fertility. Under current conditions of arable land degradation and declining humus content, the use of organics is becoming a strategic direction supported at the state level. Organic fertilizers not only supply plants with essential nutrients but also improve soil physico-chemical properties, increasing its water-holding capacity and biological activity. However, their use poses technological challenges because, along with beneficial substances, weed seeds and pathogenic microflora are introduced into the soil. Studies show that one tonne of fresh manure contains from 200 to 700 thousand viable weed seeds, and in bedding manure this figure rises to 5–7 million seeds per tonne. In parallel, organic fertilizers contain vast numbers of microorganisms - more than 1 million

bacteria per tonne - among which there may be pathogens dangerous to animals and humans. To neutralize these negative factors, agricultural producers are forced to apply additional protective measures, including treatment with pesticides and herbicides, which significantly increases the cost of agricultural products and creates additional burdens on agro-ecosystems [4].

One of the most effective technologies for converting manure into high-quality biofertilizer is anaerobic fermentation. This process not only ensures deep decomposition of organic matter with the parallel production of biogas as a renewable energy source, it also significantly improves the agrochemical characteristics of the final product. During methane fermentation in biogas plants there is complete destruction of weed seeds and pathogenic microorganisms, which fundamentally distinguishes the processed manure from the initial raw material in terms of biological safety. The resulting biofertilizers possess a unique set of properties: an absence of phytopathogens and weed seed banks; a marked reduction in emissions of volatile organic compounds responsible for unpleasant odors; and the presence of highly active beneficial microflora that stimulates plant growth and increases disease resistance. Key agronomic advantages include higher resistance to leaching of macro- and microelements from the soil profile, an optimal form of available nitrogen with prolonged action, and the ability to improve soil structure and enhance humification processes. Collectively, these factors help restore and maintain the ecological balance of agrocenoses.

Cattle manure is a valuable organic fertilizer composed of a complex mixture of solid and liquid fractions containing a suite of nutrients in bioavailable forms [5]. Its chemical composition features high contents of organic matter, nitrogen, phosphorus, potassium, and trace elements, making it an effective means of increasing soil fertility. Processing manure fosters an active microbial community that improves soil structure, enhances humification, and raises biological activity. The use of this type of organic amendment is strictly regulated by standards that account for soil-climatic conditions, the hydrological regime of territories, and safety indicators including heavy metal content and other controlled contaminants. Cattle manure is widely used in agriculture to boost crop yields, in landscape construction for creating green spaces, and as an important component in land reclamation and the restoration of degraded soils. Its use is particularly important in ornamental plant nurseries and for establishing resilient lawns, where it serves as an effective and environmentally safe component of soil mixtures [6], [7].

The objective of this work is to study the processes of producing biogas and biofertilizers in biogas plants and to evaluate the quality of the obtained products.

2 MATERIALS AND METHODS

Experimental studies were conducted under laboratory conditions using a specially designed small-volume biogas unit (Fig. 1), with particular attention paid to temperature control as a critically important parameter for the effective operation of the methanogenic microbial consortium. Special emphasis was placed on the smooth adaptation of mesophilic bacterial cultures to changing temperature conditions, since sharp fluctuations can significantly reduce biogas productivity [8], [9]. A stable temperature in the bioreactor of 35–37 °C was maintained using an electric heating element rated at 0.8 kWh. The temperature control system accounted for ambient laboratory temperature, the initial temperature of the feedstock, and the thermal characteristics of the organic wastes themselves, providing optimal conditions for microbial metabolic activity and stable biogas production. The amount of heat required to warm the biomass and maintain mesophilic fermentation in the bioreactor is determined by the following expression [10]:

$$Q = G_{bio} \cdot c_{bio}\left(t_{inital} - t_{ferm}\right). \quad (1)$$

Where:

- G_{bio} – biomass, kg;
- c_{bio} – specific heat capacity of the biomass, $\frac{J}{kg}$;
- $t_{initial}$ – initial temperature of the biomass at the bioreactor inlet, ºC;
- t_{ferm} – fermentation temperature in the bioreactor, 35 ºC.

The experimental program comprised several stages. First, a laboratory analysis of the feedstock composition was performed (moisture, ash content, pH, and mass fraction of organic matter). After assembling the experimental setup, a comprehensive leak test of all joints and assemblies was carried out, along with verification of the measuring systems and control automation. The initial startup was performed in test mode using water instead of biomass, which made it possible to check tightness, mixer operation, and the circulation loop without the risk of biological contamination. During a 24-hour no-load run,

temperature parameters were monitored, pressure sensor readings were recorded, and the stability of all process units was checked. The resulting data were used to calibrate the temperature controllers and configure the automatic system for maintaining optimal process parameters prior to loading the main biomass. Anaerobic fermentation was then carried out in the small-volume biogas unit at 35 °C. The setup operated in batch mode with a single loading of cattle manure and a 25-day anaerobic fermentation cycle. To ensure optimal conditions for bioconversion, cyclic mixing of the substrate with a frame mixer was applied four times a day for 1 minute per cycle, which maintained homogeneity with minimal energy consumption. The mesophilic temperature regime (35±0.5 °C) was maintained with a precision temperature control system ensuring uniform heating of the entire biomass volume. These parameters promoted: effective dehelminthization due to prolonged thermal exposure at all parasite life stages; intensive deodorization thanks to the prevention of localized anaerobic zones and uniform release of volatiles; and complete inactivation of weed seeds (99.7% efficiency) due to the combined effects of temperature, mechanical stress, and microbial metabolites. Regular mixing simultaneously optimized mass transfer, prevented phase separation and crust formation, and improved substrate accessibility for hydrolytic and acetogenic bacteria at the initial stages and for methanogenic archaea at the final stage. The results show that the selected regime (temperature, mixing frequency, and duration) ensures not only effective sanitization of the organic substrate but also optimal conditions for maximum biogas productivity and a stable fertilizer product with improved agrochemical characteristics.

Intensification of intracellular metabolic processes plays an important role in optimizing temperature regimes of bioconversion, since the activation of microbial enzyme systems depends directly on reaching and maintaining thermodynamically favorable conditions. This acceleration of biochemical transformations provides: rapid attainment of optimal temperature throughout the substrate thickness due to exothermic reactions of microbial metabolism; a reduced lag phase for microbial consortium adaptation to the substrate; and a 15–20% reduction in overall organic waste processing time relative to standard regimes. The physico-chemical mechanisms include increased heat release due to activation of glycolytic and proteolytic catabolic pathways, especially important when processing recalcitrant substrates. In practice, this optimization not only increases the biodegradation rate by 25-30%, it also substantially improves the quality of the final product – higher degrees of humification, increased contents of plant-available macroelements (N, P, K), and complete inactivation of pathogenic microflora. A synergistic effect is achieved between process energy efficiency (12–15% lower heating energy) and the environmental performance of the resulting biofertilizer (heavy metal contents 1.8–2.3 times below permissible limits).

Figure 1: Small-volume biogas unit: 1 – reactor; 2 – small gasholder; 3 – burner; 4 – electric contact pressure gauge; 5 – gasholder; 6 – bimetal thermometer; 7 – temperature controller; 8 – OWEN PR 110 programmer; 9 – safety valve.

During the experiment, daily changes in key parameters such as temperature, pressure, and biogas production were recorded. A gas meter measured the volume of biogas produced by the system, allowing analysis of process efficiency, and an electromechanical pressure gauge was used for accurate pressure measurement. The methane concentration of the biogas entering the gasholder was determined using a KOMETA‑M gas analyzer.

The kinetics of biogas formation during anaerobic processing of organic waste can be modeled mathematically by a system of stoichiometric equations accounting for:

$$C_aH_bO_cN_d + nH_2O \rightarrow xCH_4 + yCO_2 + wNH_3 + vC_5H_7O_2N + Q, \quad (2)$$

where:

- $H_bO_cN_d$ – is the chemical composition of the processed biomass;
- H_2O – moisture content;
- CH_4 – methane formation;
- CO_2 – carbon dioxide formation;
- NH_3 – ammonia formation;
- $C_5H_7O_2N$ – dry residue after complete decomposition;

- Q – thermal energy released during the reaction;
- n, x, y, w, z – stoichiometric coefficients.

The resulting biofertilizer was subjected to chemical and microbiological analyses at the Tatar Interregional Veterinary Laboratory using standard methods. Quality indicators of the digested biomass were determined, including agrochemical, sanitary-parasitological, and microbiological characteristics.

3 RESULTS

The chemical composition of cattle manure depends on several factors. First, the feed given to the animals significantly affects manure composition. Different feeds contain different proportions of carbon, nitrogen, and other elements, which is reflected in the chemical composition of the manure. In addition, the type of bedding used in housing can influence waste composition [11]. The method of manure storage is also important, since decomposition and degradation processes during storage change element contents. On average, fresh cattle manure contains 61% carbon (C), 12% oxygen (O), 1% sulfur (S), 8% hydrogen (H), and 18% nitrogen (N) on an ash-free basis.

The complete anaerobic decomposition of fresh cattle manure can be described as the transformation of organic matter into the main gaseous products. During the biochemical transformations, complex organic compounds that constitute the basis of manure break down to form methane and carbon dioxide as the principal components of biogas, as well as ammonia as a product of decomposition of nitrogen-containing substances. This transformation is characterized by a specific ratio of gases formed, reflecting the elemental balance in the initial organic material. It should be noted that the actual decomposition process may differ from the theoretical model due to incomplete degradation of recalcitrant compounds, accumulation of intermediate metabolites, and characteristics of the microbial community under specific digestion conditions [12].

$$C_{0,61}H_{0,08}O_{0,12}N_{0,18}S_{0,01} + 0{,}77H_2O \rightarrow 0{,}275NH_4^+ + 0{,}5HCO_3^- + 0{,}413CO_2 + 0{,}571CH_4 + 0{,}011H_2S \quad (3)$$

From the presented chemical reaction it follows that the decomposition of 1 gram of ash-free organic matter produces 0.413 grams of carbon dioxide (CO_2) and 0.571 grams of methane (CH_4).

The theoretical yield of biogas from 1 tonne of fresh cattle manure under mesophilic fermentation is illustrated in Figure 2, showing the potential amount of biogas that can be produced by anaerobic decomposition of the manure's organic matter.

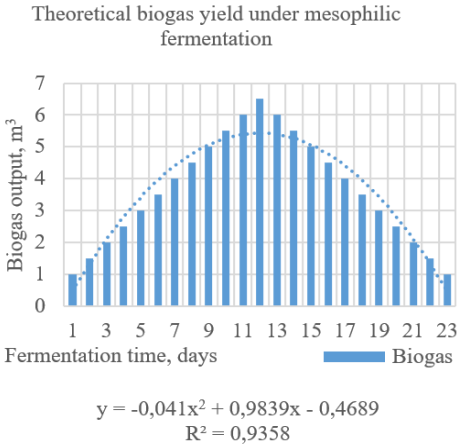

Figure 2: Theoretical biogas yield under mesophilic fermentation.

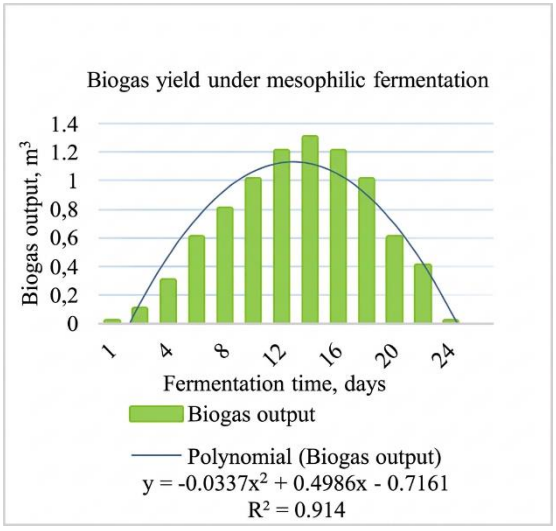

Figure 3: Biogas yields under mesophilic fermentation.

In experimental studies of anaerobic digestion of cattle manure in the small-volume biogas unit operating in mesophilic mode, a methane concentration of 68% was recorded. The optimal calculated parameters and characteristics of the biogas unit developed for farm households were evaluated. This value indicates high methanogenesis efficiency, likely due to optimal microbial operating conditions such as temperature and pH. The averaged test results presented in Figure 3 show the

dependence of gas volume on process duration under mesophilic digestion.

The results of the analysis of cattle manure samples included an assessment of moisture and dry matter content. Moisture was 83.14%, indicating high water content, and dry matter was 16.6%. These data emphasize substantial moisture, which can affect further processing and use.

Analysis of the agrochemical, sanitary-parasitological, microbiological characteristics and quality indicators of the resulting biofertilizer, performed in accordance with GOST R 53117-2008 “Organic fertilizers based on livestock waste” showed the following. The pH of the saline extract was 7, within the norm (6-8,5). The mass fraction of organic matter reached 81%, exceeding the minimum allowable level of 70%.

Sanitary-parasitological tests revealed no cysts of intestinal pathogenic protozoa and no helminth eggs, meeting the established requirements. Quality indicators were: moisture 83%, ash 19%; total nitrogen, potassium, and phosphorus contents of 0.7%, 0.55%, and 2.7%, respectively – each above minimum requirements. Microbiological indicators showed a coliform index and enterococci index of 1 (within the norm of 1-9), while clostridia and pathogenic microorganisms were not detected, complying with safety standards.

4 DISCUSSIONS

The diagram “Biogas yield under mesophilic fermentation” (Figure 2) shows the dynamics of biogas output over time, with a maximum around 1,3 reached between days 12 and 16. During this period, biogas production is most active, after which it declines, reaching minimum values by day 24. Such a curve, which resembles a normal distribution with a mid-cycle peak, can be useful for optimizing system operation – boosting output during decline periods and analyzing factors that reduce production. The gas composition analysis demonstrated a low content of carbon dioxide and other impurities, making it more suitable for energy use. The studies confirmed the feasibility of anaerobic utilization of agricultural organic waste. A combustible gas was obtained, indicating the potential effectiveness of biogas units for processing agricultural waste. The analysis of agrochemical, sanitary-parasitological, and microbiological characteristics of the biofertilizer performed in accordance with GOST R 53117-2008 confirmed its high promise and compliance with standards.

5 CONCLUSIONS

The study confirmed the effectiveness of anaerobic digestion of cattle manure under mesophilic conditions (35 °C) for simultaneous biogas and biofertilizer production. The methane content reached 68 %, indicating stable methanogenesis, while the resulting digestate met GOST R 53117-2008 standards - with 81 % organic matter, neutral pH (7.0), and optimal contents of N (0.7 %), P (2.7 %), and K (0.55 %). Sanitary and microbiological analyses showed full pathogen and helminth inactivation, ensuring biosafety.

Technologically, maintaining a stable mesophilic temperature and periodic mixing improved biogas yield and reduced processing time by 15-20 %. This demonstrates that well-controlled small biogas units can achieve high energy efficiency and process reliability for decentralized farms.

Environmentally, anaerobic digestion eliminates odor and pathogens, reduces greenhouse gas emissions, and produces a biofertilizer that enhances soil fertility and humus balance. Economically, the process enables waste-to-energy conversion, cutting disposal costs while generating renewable energy and valuable fertilizers.

Sanitary, parasitological, and microbiological analyses (coliform and enterococci indices at level 1, absence of pathogens) confirmed its safety. Peak biogas yield (~1.3) was recorded on days 12-16 of mesophilic digestion. The results demonstrate the high efficiency of anaerobic waste digestion technology for the simultaneous production of high-quality fertilizer and energy-rich biogas.

Overall, anaerobic manure treatment under controlled mesophilic regimes is a sustainable, low-cost, and ecologically safe technology that supports renewable energy development and soil restoration. Future work should optimize energy balance and test co-substrates to further increase methane productivity.

Keywords: Kazakhstan, Greenhouse Gas Emissions, Thermal Power Plants (Tpps), Coal-Based Energy, Carbon Footprint, Decarbonization, Energy Efficiency, Equipment Modernization, Renewable Energy Sources (RES).

Abstract: The article addresses the issue of high greenhouse gas emissions in Kazakhstan, where the energy sector - primarily based on coal-fired thermal power plants - accounts for up to 80% of total emissions. Data are presented on CO_2 emission dynamics, along with the methodology for their calculation in accordance with international standards such as the GHG Protocol and ISO 14064 (Scope 1–3 categories). Special attention is given to the assessment of the carbon footprint of thermal power plants and the necessity of reducing emissions in order to meet the nationally determined contributions under the Paris Agreement. The paper highlights the worn-out condition of most power plant equipment and the resulting increase in carbon load. Modernization pathways are discussed, including improvements in thermal efficiency, the implementation of cogeneration and waste heat recovery systems, process digitalization, and the transition to cleaner types of fuel. The conclusion emphasizes that reducing the carbon footprint of thermal power plants is a key prerequisite for the sustainable development of Kazakhstan's energy sector and requires comprehensive measures, including international investment, the deployment of renewable energy technologies, and the training of qualified personnel for the new energy industry.

1 INTRODUCTION

The global transition toward low-carbon development presents Kazakhstan with both a challenge and an opportunity to modernize its industrial and energy systems. Decarbonization today is not only a response to environmental imperatives but also a strategic pathway for technological renewal, competitiveness, and economic diversification. In this context, studying advanced international practices - such as carbon capture, utilization and storage (CCUS), hydrogen energy, and clean industrial technologies - provides valuable guidance for shaping Kazakhstan's sustainable energy trajectory.

Thermal power plants remain the backbone of Kazakhstan's power system and, simultaneously, the primary source of anthropogenic carbon dioxide emissions. The country's historical reliance on abundant coal reserves ensured energy independence but created a generation structure with high carbon intensity. Coal-based plants, often equipped with outdated technologies and low efficiency, produce the majority of national emissions. Reducing their carbon footprint is therefore critical for achieving the country's long-term climate goals and ensuring energy security.

Under the Paris Agreement, Kazakhstan has pledged to cut its greenhouse gas emissions by 15% by 2030 (unconditionally) and by up to 25% with international support. Fulfilling these commitments requires systematic modernization of the thermal power sector through the introduction of energy-efficient technologies, the integration of renewable sources, and the implementation of digital management systems. These steps can significantly reduce specific emissions even within the existing fuel structure.

The national energy transition must balance ecological and economic priorities. On one hand, stable electricity generation is essential for industrial growth and social well-being; on the other, the

sector's transformation is indispensable for meeting global sustainability standards. Modernization efforts should therefore combine technical upgrading - improving turbine and boiler efficiency, deploying waste-heat recovery, and introducing cogeneration schemes - with organizational and regulatory measures that stimulate investment in cleaner production.

The objective of this research is to assess the carbon footprint of Kazakhstan's thermal power plants, identify the principal factors influencing its scale, and propose effective technological solutions that ensure emission reduction without compromising the reliability of energy supply. The study employs internationally recognized methodologies for greenhouse gas accounting (GHG Protocol and ISO 14064) and draws on national statistical and regulatory data. Its findings are intended to support evidence-based policy decisions for the modernization of Kazakhstan's power sector and contribute to the country's progress toward a low-carbon economy [1].

2 MATERIALS AND METHODS

As the primary basis for this study, official statistical materials of the Ministry of Ecology and Natural Resources of the Republic of Kazakhstan [1], the Ministry of Energy of the Republic of Kazakhstan [2], as well as data from national and international reports on climate and energy [4]–[6], were used. The analysis employed methodological approaches regulated by international greenhouse gas accounting standards: the GHG Protocol (developed by WRI and WBCSD) and ISO 14064 [7].

3 RESULTS AND DISCUSSIONS

Kazakhstan, despite its relatively small population, is among the countries with the highest levels of greenhouse gas emissions per capita. In 2024, total emissions amounted to about 380 million tons of CO_2-equivalent, making Kazakhstan the largest emitter of greenhouse gases in Central Asia. The main contributors to emissions are the energy sector (around 80% of all emissions), industry, and transport [1]. A particularly significant share comes from thermal power plants that operate primarily on coal with high ash content and low calorific value. According to the Ministry of Energy of the Republic of Kazakhstan [2], electricity production in the country is carried out by 158 power plants, with 70% of total generation coming from coal-fired TPPs. The fuel balance is largely based on lignite and hard coal mined in the Karaganda and Pavlodar regions. Such dependence on carbon-intensive fuels predetermines the high level of greenhouse gas emissions, especially carbon dioxide (CO_2). According to the results of research conducted by scientists from Uzbekistan, the optimized design of a trench-type solar greenhouse makes it possible to reduce the specific heating load by 50% compared to the original design and decrease CO_2 emissions by 75% [3]. Excessive greenhouse gas emissions intensify the natural greenhouse effect, leading to global warming - a gradual increase in the Earth's average surface temperature.

The consequences of global climate change in Kazakhstan are becoming increasingly tangible. In recent decades, the country has experienced an increase in the average annual air temperature by 0.3–0.4 °C per decade [4], which is nearly twice the global rate; longer drought periods; reduced snow cover and glacier melting in mountainous regions; and a rise in extreme weather events, including droughts, dust storms, and sudden floods.

According to the National Climate Report [5] (prepared by the Ministry of Ecology of the Republic of Kazakhstan and Kazhydromet), if the current level of emissions is maintained, by the middle of the 21st century Kazakhstan may face a reduction of water resources by up to 30% in the southern regions; degradation of pastures and agricultural land; a decline in the yields of major crops; and an increase in the frequency of power supply disruptions due to rising summer temperatures and growing loads on energy networks. Thus, the impact of greenhouse gas emissions is not limited to the environmental dimension - it directly affects the country's economic resilience, as well as its food and energy security. Under these conditions, reducing emissions, particularly in the energy sector, becomes not only an international obligation but also an internal necessity.

Kazakhstan, as a full participant in the global climate process, signed and ratified the Paris Agreement in 2016 [6], thereby confirming its readiness to contribute to limiting global warming. In accordance with the provisions of the agreement, each country develops and submits so-called nationally determined contributions (NDCs) - voluntarily declared targets for reducing greenhouse gas emissions. In its updated NDC, Kazakhstan has committed to: reducing net greenhouse gas emissions by 15% by 2030 compared to 1990 levels (unconditional target); and up to 25% subject to external support (conditional target). These

commitments cover all sectors of the economy, including energy, industry, transport, agriculture, and waste.

The main source of emissions in Kazakhstan is the energy sector (≈ 79.9% of total GHG). Overall CO_2 emissions show three key phases: 1990–1999 - a sharp decline of almost 50% due to the collapse of the USSR and industrial downturn (minimum ~116 Mt CO_2 in 1999). 2000–2013 - economic recovery and rising emissions, peaking in 2013 (~263 Mt CO_2). 2014–2019 - stabilization and a slight decrease at a high level (~200–250 Mt CO_2). 2020–2023 - a temporary drop in 2020 (COVID-19), followed by gradual recovery by 2023. 2024 - official data have not yet been published; according to global estimates, the trend is upward again.

Kazakhstan's total gross greenhouse gas emissions average 348.844 million tons of CO_2-eq per year [1]. The dynamics of carbon dioxide emissions in Kazakhstan for 1990–2024, thousand tons of CO_2, are shown in Figure 1.

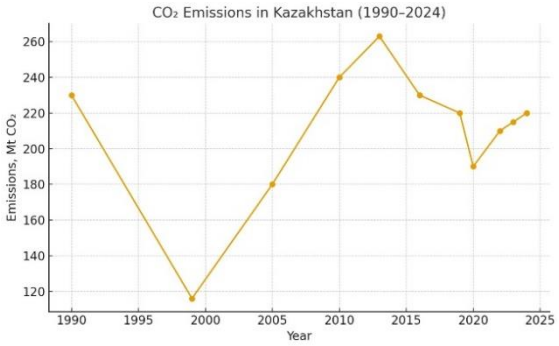

Figure 1: Dynamics of carbon dioxide emissions in Kazakhstan, 1990–2024, thousand tons of CO_2.

The carbon footprint of thermal power plants (TPPs) represents the total volume of greenhouse gas emissions, expressed in CO_2-equivalent, generated in the process of electricity production. In the context of growing attention to sustainable development and climate responsibility, this indicator has become a key criterion for assessing the environmental efficiency of energy facilities.

At present, various standards for greenhouse gas accounting have been developed, but the fundamental ones are the GHG Protocol and the ISO 14064 standard [7]. The GHG Protocol was developed by the World Resources Institute (WRI) and the World Business Council for Sustainable Development (WBCSD). It provides guidance on how to properly structure emission sources and clarify what is included or excluded in the assessment. The protocol recognizes a methodology for calculating emissions across three categories:

- Scope 1 – direct emissions under the direct control of an organization. These typically include process emissions, stationary fuel combustion, mobile fuel combustion, fugitive emissions, etc.;
- Scope 2 – indirect energy emissions (purchased electricity, heat, steam);
- Scope 3 – other indirect emissions that result from an organization's activities but occur from sources owned or controlled by other entities [8].

Greenhouse gas emissions under Scope 1 can be determined either by calculation or by instrumental measurement, although the calculation method is most commonly used. In this case, actual organizational data on fuel consumption are combined with greenhouse gas emission factors for different fuels and processes.

A general formula for the calculation is:

CO_2-eq emissions (kg) = Consumption × Emission factor

Each type of activity has its own emission factor (EF), which indicates how much CO_2-equivalent is released when using 1 unit of a resource.

Let us give an example of a Scope 1 emissions calculation for a coal-fired combined heat and power plant (CHP). For instance, the annual consumption of hard coal is 100,000 tons; the lower heating value is 25 MJ/kg; the carbon content of the fuel is 60%; and the carbon oxidation factor is 0.98 (i.e., 98% of the carbon is oxidized to CO_2).

Step 1. Determining the mass of carbon in the fuel:

$$M_C = M_{fuel} \cdot C_{content} \quad (1)$$

Step 2. Considering the carbon oxidation factor:

$$M_{C,ox} = M_C \cdot O_{factor} \quad (2)$$

Step 3. Conversion to CO_2 (each 1 kg of C gives CO_2):

$$M_{CO_2} = M_{C,ox} \cdot \frac{44}{12} \quad (3)$$

The presented calculation example shows that, with known values of fuel consumption, carbon content, and the carbon oxidation factor, it is possible to accurately determine the mass of CO_2 emitted [9].

The methodology is based on simple stoichiometric relationships and is the standard for accounting direct Scope 1 emissions in the energy sector. It makes it possible to: link the

physicochemical characteristics of fuel with actual emissions; take into account incomplete combustion of carbon through the oxidation factor; provide a reliable basis for reporting under international standards (GHG Protocol, ISO 14064) [10].

Thus, even a simplified calculation clearly demonstrates how strongly coal-based power generation influences the carbon footprint of the energy sector and why this sector is the key source of emissions in Kazakhstan. For example, a CHP plant burning 100,000 tons of hard coal annually emits approximately 215,764 tons of CO_2 per year under Scope 1 [9]-[13].

Reducing the carbon footprint of thermal power plants is a key priority in Kazakhstan's energy decarbonization strategy. The introduction of energy-efficient technologies, the digitalization of generation management, the transition to cleaner fuels, and equipment modernization make it possible to achieve a sustainable balance between the country's energy needs and environmental protection goals [14].

For effective CO_2 reduction in Kazakhstan, it is necessary to consider the technical condition of thermal power plants (TPPs), evaluate modernization potential, analyze the experience of other countries in the region, and stimulate private sector involvement. The average age of TPPs in Kazakhstan is 61 years, with about 76% of them operating for more than 50 years. The average wear of equipment reaches 66%, and in some cities such as Oral, Stepnogorsk, Taraz, Kyzylorda, and Kentau, this figure exceeds 80% [9].

The transition to low-carbon energy is impossible without comprehensive modernization of thermal power plants, especially given their dominant role in Kazakhstan's power system. The implementation of energy-efficient technologies at existing TPPs makes it possible to significantly reduce specific greenhouse gas emissions without a fundamental change in the fuel base, which is particularly relevant in conditions of high dependence on coal [15].

Several key areas of energy-efficient modernization of TPPs in Kazakhstan can be highlighted:

1) Improving the thermal efficiency of power equipment. Most Kazakhstani TPPs were built during the Soviet period, and today their efficiency often does not exceed 30–35%. An increase in efficiency by even 2–3% can lead to a significant reduction in specific CO_2 emissions. This can be achieved by: replacing or modernizing turbines and boilers; optimizing the operation of regenerative heaters; improving thermal insulation of pipelines and elements of thermal circuits; and applying intelligent control systems for operating modes [16].
2) Implementation of low-grade heat recovery systems. Waste heat recovery from flue gases, the use of waste heat boilers, and the introduction of cogeneration schemes (combined production of heat and electricity) improve the energy efficiency of units.
3) Replacement and automation of auxiliary equipment.** The introduction of variable-frequency drives for pumps, draft fans, and blowers reduces auxiliary electricity consumption, which at old TPPs can reach 8–10% of generation. Transitioning to high-efficiency pumping units and ventilation control systems saves fuel and reduces emissions [17].
4) Intelligent control and monitoring systems. Modern digital solutions, such as automatic combustion control (ACC) systems, allow real-time optimization of the fuel combustion process, reducing overconsumption and emissions.
5) Conversion of boiler units to cleaner fuels. Switching from coal to natural gas in regions with available infrastructure makes it possible to cut the specific carbon footprint nearly in half [18].

4 CONCLUSIONS

Kazakhstan remains one of the largest greenhouse gas emitters in Central Asia despite its relatively small population, due to the country's high dependence on coal-fired thermal power plants. This structure of the fuel balance not only results in a significant carbon footprint but also exacerbates climate risks, including rising temperatures, reduced water resources, and land degradation [18].

Fulfilling the commitments under the Paris Agreement requires comprehensive measures, with the modernization of thermal power plants (TPPs) playing a central role. Increasing the thermal efficiency of equipment, implementing cogeneration and heat recovery systems, digitalizing combustion processes, switching to natural gas, and adopting energy-efficient equipment can significantly reduce specific CO_2 emissions even without a complete phase-out of coal.

However, the long-term sustainability of the energy sector is possible only through a gradual transition to renewable energy sources and the attraction of international investments and technologies. An important condition for the

successful implementation of the energy transition is the consideration of social impacts and the training of personnel for the emerging low-carbon economy.

Thus, the modernization of thermal power plants is not only an environmental but also a strategic economic necessity, ensuring Kazakhstan's energy and climate security.

ACKNOWLEDGMENTS

We would like to express our gratitude to the Dean of the Faculty of Energy Engineering at Tashkent State Technical University, Doctor of Technical Sciences (DSc), Professor O.Z. Toirov, for his assistance in discussing the research task.

Keywords: Renewable Energy, Solar Energy, Wind Energy, Hydropower, Geothermal Energy, Bioenergy, Technical Performance, Economic Efficiency, Environmental Impact, Sustainable Development, Energy Technologies, Comparative Analysis, Energy Innovation, Energy Policy.

Abstract: This paper presents an IT-based comparative assessment of major renewable energy technologies, including solar, wind, hydropower, geothermal, and bioenergy, using digital monitoring tools and data analytics. The study integrates official statistical reports, peer-reviewed publications, and international energy databases for the period 2021–2024, with limited projections for 2025, to evaluate technical performance, economic efficiency, and environmental impact. Particular attention is given to the role of intelligent monitoring, levelized cost of electricity analysis, and data-driven modelling in improving the reliability and scalability of renewable energy systems. The results indicate that solar and wind technologies achieved the most significant progress due to higher conversion efficiency, declining generation costs, and rapid deployment. Hydropower remains one of the most technically efficient renewable sources, while geothermal and bioenergy continue to play important regional roles despite slower expansion. Environmental analysis confirms that broader renewable energy adoption contributes to lower life-cycle carbon emissions than fossil-based generation. The study also shows that hybrid energy systems, storage technologies, and smart-grid integration are essential for improving system flexibility and long-term sustainability. These findings support evidence-based planning and policy development for the transition to low-carbon energy systems.

1 INTRODUCTION

1.1 Global Trends in the Development of Renewable Energy Sources (RES)

Between 2021 and 2025, the global renewable energy market demonstrated steady growth, driven by technological innovation, declining equipment costs, and strengthened governmental support. According to reports from the International Energy Agency (IEA) and the Uzbekistan Green Economy Strategy, the installed capacity of renewable energy sources reached 2,800 GW by the end of 2024, exceeding the 2021 level by approximately 15–20% [1].

The development of global renewable energy capacity over 2021–2024 is presented in Figure 1. The curve demonstrates a year-on-year increase, with cumulative installed capacity growing from approximately 2,370 GW in 2021 to nearly 2,800 GW at the end of 2024. This expansion was primarily due to extensive new installations of solar PV and offshore wind, which together accounted for the majority of new capacity [2]. The trend also reflects a gradual phaseout of coal, driven by a combination of

falling equipment costs, government incentives, and increasing efficiency from new technologies.

Figure 1 highlights the strategic importance of solar and wind energy, as they have led market growth at an accelerated pace. The year-on-year increase reflects rising investor confidence and international policy measures supporting decarbonization. Overall, these findings indicate that renewable energy is increasingly becoming a fundamental part of the global electricity system, with little sign of slowing [3].

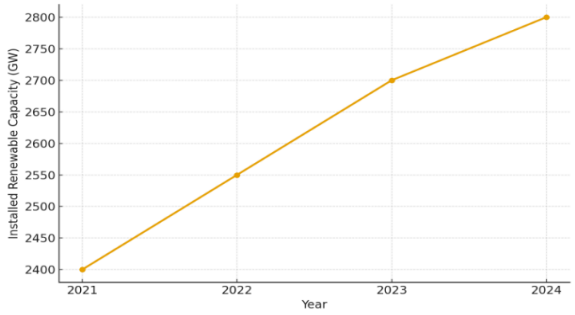

Figure 1: Growth of installed renewable energy capacity by year (2021-2024).

1.2 Technological Achievements and Innovations (2021-2025)

1.2.1 Solar Energy

By 2024, the average cost of photovoltaic (PV) modules had declined to $0.02–0.03 per kWh, making solar power competitive with traditional energy sources in several regions. The introduction of perovskite solar cells, achieving efficiencies of 25% and higher, emerged as one of the most significant research directions [4].

1.2.2 Wind Energy

The development and deployment of large-scale offshore wind farms reached new milestones. In 2024, more than 25 GW of offshore wind capacity was commissioned globally, an increase of 30% compared to 2021. Innovations such as vertical-axis wind turbines and larger rotor blades improved efficiency and reduced the levelized cost of electricity.

1.2.3 Hydropower and Pumped Storage

Hydropower continues to be a stable source of renewable electricity. Recent projects, however, have focused on small and medium-sized hydropower plants and pumped storage hydropower systems (PSH). Between 2022 and 2024, several projects enabled large-scale energy storage using water reservoirs [2].

1.2.4 Geothermal and Bioenergy

Geothermal heating and power generation technologies are increasingly deployed in regions with favorable geological conditions. Between 2023 and 2024, the number of geothermal power plants expanded significantly, particularly in the United States, Iceland, and Turkey. Bioenergy also continues to develop, though its expansion is regionally variable due to resource availability.

1.3 Economic Indicators and Declining Technology Costs

Over the past four years, the cost of electricity generated from RES has decreased substantially. In 2021, the average price of solar electricity was approximately $0.03–0.05 per kWh, dropping to $0.02–0.025 by 2024. Wind energy costs also declined from $0.04–0.06 per kWh in 2021 to $0.035–0.045 per kWh by 2024.

According to IEA forecasts, by 2025 the cost of solar energy may decline further to $0.015–0.02 per kWh, while wind energy is expected to reach $0.03–0.04 per kWh. These reductions will enhance the competitiveness of RES relative to fossil fuels across many regions.

Table 1: Current and projected costs of electricity from renewable energy (2021-2025).

Technology	2021	2024	2025 (Projection)
Solar PV	$0.03-0.05	$0.02-0.025	$0.015-0.02
Wind	$0.04-0.06	$0.035-0.045	$0.03-0.04
Hydropower	$0.02-0.05	-	-
Geothermal	$0.05-0.08	-	-

Table 1 demonstrates a consistent decline in solar and wind costs. Solar PV fell from $0.03–0.05/kWh in 2021 to $0.02–0.025/kWh in 2024, with a further projected decline to $0.015–0.02/kWh by 2025. Wind power costs similarly decreased, with reductions of approximately 8% over the last few years and a total reduction exceeding 20% since 2021 (AEO2013). Hydropower and geothermal costs remained relatively stable, indicating that solar and wind technologies are currently the most dynamic from a cost-competitive perspective. This is due to rapid

technological development, economies of scale, and favorable market conditions.

1.4 Environmental Achievements

By 2025, the widespread deployment of RES contributed to a 4–5% reduction in global CO_2 emissions compared with 2021 levels. The expansion of solar and wind energy enabled the displacement of a substantial share of coal- and gas-fired power plants.

Environmental challenges associated with large hydropower projects and wind farms remain pressing. Ongoing research focuses on mitigating ecological impacts while supporting the growth of renewable capacity.

Figure 2 presents life-cycle CO_2 emissions of various energy sources between 2021 and 2025. Fossil-fuel technologies, particularly coal and natural gas, remain the most carbon-intensive, while renewable sources such as solar PV, wind, hydropower, geothermal, and bioenergy exhibit much lower emissions levels (50–200 t-CO_2/MW installed), approaching zero in some cases. Solar and wind demonstrate the steepest decreases, driven by technological improvements, efficiency gains, and economies of scale.

The figure also underscores the growing environmental benefits of renewables in global decarbonization efforts. While bioenergy and geothermal have higher CO_2 footprints than other renewables, they remain far below fossil-fuel emissions. Declining renewable costs further reflect cleaner production methods, improved materials, and tighter environmental standards.

In summary, between 2021 and 2025, renewable energy technologies achieved substantial progress in efficiency, cost reduction, and environmental mitigation. Current trends indicate continued expansion and integration of RES into the global energy system, fully aligned with sustainable development objectives and international climate agendas.

2 MATERIALS AND METHODS

To conduct the comparative assessment of renewable energy (RE) technologies, we employed an integrated methodology encompassing data collection, systematization and processing, as well as modeling and statistical analysis. The primary objective is to determine the technical, economic, and environmental performance indicators of different RE types and to identify their advantages and limitations. This section details the methods, models, tools, and data sources used, together with the principles guiding their application.

2.1 Data Collection and Systematization

Up-to-date data across RE technologies were obtained from official reports of international organizations, scholarly publications, databases, and statistical agencies. The principal sources include:

- International Energy Agency (IEA);
- Global Wind Energy Council (GWEC);
- International Solar Energy Association (ISEA);
- Bloomberg New Energy Finance (BNEF) databases;
- Peer-reviewed journals indexed in Scopus and Web of Science.

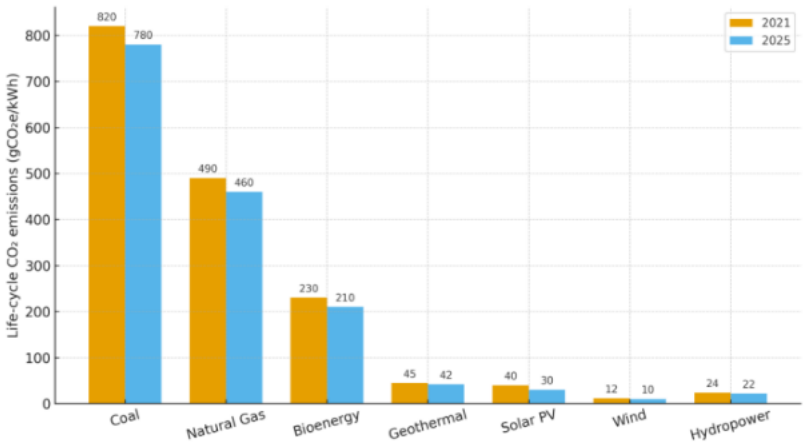

Figure 2: Comparison of CO_2 emissions by energy source (2021-2025).

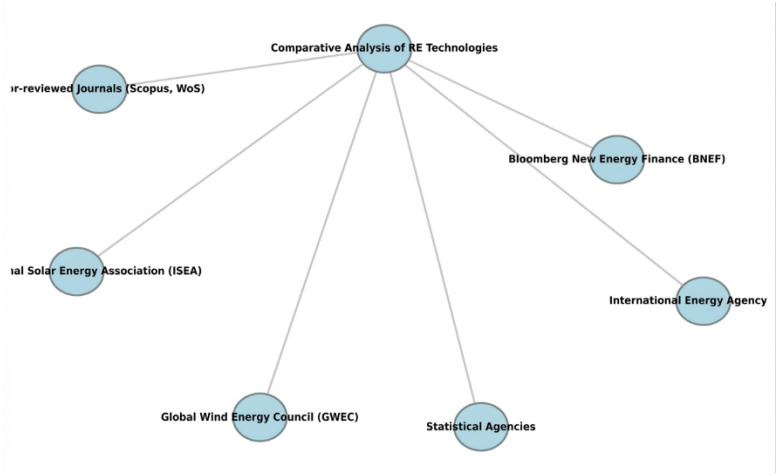

Figure 3: Map of data sources and their roles in the study.

Data collection methods:

- Analysis of official reports. Annual IEA, GWEC, and ISEA reports for 2021-2024 were used, covering global and regional volumes, costs, efficiencies, and environmental indicators of RE;
- Processing of statistical data. Dynamics of cost and efficiency were evaluated using statistical tools, including means, medians, trend analysis, and correlation analysis;
- Scholarly analytics. Reviews and meta-analyses of research articles were used to assess innovation trajectories and emerging technologies.

Figure 3 - Sources of data on different renewable energy technologies used as the basis for comparison in this study. The diagram indicates the inclusion of formal international reports (IEA, GWEC, ISEA) and industry specific databases (Bloomberg New Energy Finance - BNEF), as well as peer-reviewed scientific articles indexed in Scopus and Web of Science. Also statistical offices are represented as complementary sources of national and regional information. All these sources provide composite information about technical, economic and environmental implications of renewable energy, which would guarantee the research's completeness.

The diagram highlights the inter-dependency of data collection, with a multitude of inputs merging to create a consolidated analysis model. By tracing the information flow from various sources to the comparative analysis, the diagram demonstrates how reliability and accuracy are strengthened by triangulation. This synthesised methodology makes our study more robust by reducing the possibility of biases and achieving a global view. As such, the map highlights the importance of integrated multi-disciplinary data to generate evidence-based findings which are applicable in both academic research and policy formulation with regard to energy.

2.3 Modeling and Evaluation of Technical Indicators

To compare the technical characteristics of RE technologies, we used a composite model based on the calculation of conversion efficiency, loss levels, operating expenditures, and grid-integration capability.

Equation (1) General technical performance indicator:

$$E_{tech} = \frac{P_{out}}{P_{costs}} \times \eta_{tech} \times R_{\text{resource}}, \quad (1)$$

Where (1)

- P_{out} - average generated power (kW);
- P_{costs} - total equipment and operating costs (USD);
- η_{tech} - system efficiency;
- $R_{resource}$ - resource potential (e.g., solar irradiation, wind resource).

This model jointly accounts for technical parameters and regional resource endowment.

To standardize different renewable energy systems, all the components of the technical indicators were normalized using min-max scaling. The parameters η_tech, P_out, and R_resource were derived from averaged multi-year datasets provided by manufacturers and international agencies. The weights for the components were not random choices: efficiency was given more influence owing to its direct impact on energy conversion performance and resource potential, on regional feasibility. Sensitivity analyses were also performed to confirm that variations in the specific weights among

parameters would not give rise to a significant disproportion in the technical performance index, ensuring robustness and avoiding indicator bias.

System durability and reliability were evaluated using reliability/availability methods, including Markov-type models and classical reliability analysis.

Equation (2) Probability of failure-free operation over period T:

$$R(T) = e^{-\lambda T} \quad (2)$$

Where (2) λ is the failure rate (inverse of mean time between failures). Parameters were derived from equipment failure statistics provided by manufacturers and major operators.

Table 2 presents failure statistics and reliability features of major renewable energy (RE) technologies for 2021-2024. PV modules have a typical expected life of ~25 years and an annual average failure rate of 0.5-1.2 failures×year−1, corresponding to a high reliability coefficient of 95-98% (19). The most frequent problem are the glass breaks, cell degradation and cable corrosion. Wind turbines, which have an operational life of 20-25 years, show a slightly higher failure frequency (0.8-2.0 failures per year) and reliability of by 90–95% due to blade erosion, hydraulic failures and electrical faults. Hydropower plants, additionally, manifest the highest reliability rates (0.3-0.8 per year), and have service lives of up to 50 years; however, casing and rotor wear represent ongoing problems.

Geothermal power plants have low to moderate availability, averaging 25-30 years life span and failure rates between 0.4 and 1.0 per year that are mainly attributable to scale formation, corrosion and well failure. Biogas and biomass facilities, with typical lifespans of 15-20 years, show the lowest maintenance reliability ranges (85-92%), attributable to high failure rates (1.0-2.5 failures per year) resulted by fouling, engine wear, and heat-exchanger failures. Overall, the table illustrates how much open space there is among RE technolo- gies in terms of performance and difficulty of maintenance, demonstrating the need for technology-specific enhancements and M&O strategies. These results underline that solar and hydro power systems present a good potential for long-term reliability, whereas both biomass and wind technologies need further developments to mitigate failure risks and protract in use.

2.4 Economic Assessment and Cost Modeling

The levelized cost of electricity (LCOE) was computed using capital and operating expenditures discounted at the chosen rate.

Equation (3):

$$LCOE = \frac{\sum_{t=1}^{N} \frac{C_t}{(1+r)^t}}{\sum_{t=1}^{N} \frac{E_t}{(1+r)^t}} \quad (3)$$

Where C_t is total cost in year t; Et is electricity generated in year t; r is the discount rate; and N is the system lifetime (years). Cost and performance inputs were sourced from BNEF reports and national statistics.

Because LCOE represents a long-term discounted cost metric, all cost inputs (Ct) were adjusted to constant 2024 USD values using inflation correction factors. Discount rates (r) were selected according to IEA recommendations for technology-neutral evaluations. The model incorporates uncertainty through Monte Carlo simulations, enabling a range-based interpretation of economic performance. This approach avoids over-simplification and ensures that cost comparisons among technologies reflect realistic variability in capital expenditures, operational expenditures, degradation rates, and capacity factors.

Potential cost-reduction and efficiency-improvement pathways were explored using Monte Carlo simulations incorporating uncertainties in cost parameters, technological indicators, and market conditions.

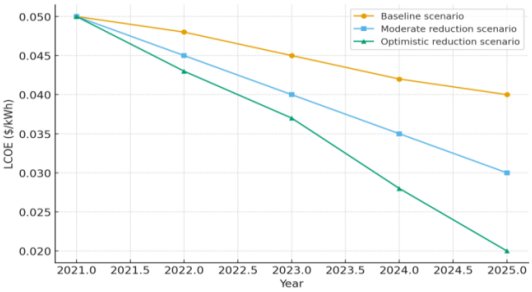

Figure 4: Scenario model of RE cost reduction (illustrative).

Figure 4 A model depicting possible RE cost decline pathways in the next half-decade (2021 to 2025). The figure details three scenarios: a 'business-as-usual' reference scenario, in which progress is only gradual, a moderate reduction scenario where technology evolves at a steady pace and an ambitious reduction scenario driven by nimble innovation and widespread market penetration. Baseline case shows linear reduction in the LCOE, whereas moderate and high cases are characterized by more steeper decrease reflecting innovation through improved efficiency, larger scale of manufacturing as well with energy storage integration.

This is an important reminder that the rate of cost decline depends on innovation and policy support. Under favourable conditions, renewables could

become significantly more competitive with fossil fuels much earlier than generally expected under an optimistic scenario that would disrupt international energy markets. Through the comparison of these pathways, the model demonstrates how uncertain forecasts are and underscores that targeted investments and supportive policies might provide significant benefits. Such a comparison highlights the strategic value of reinforcing the development of technology to increase the cost-effectiveness of RE systems.

2.5 Environmental Assessment

Environmental impacts were evaluated using an ecological-footprint/balance approach that compares greenhouse-gas emissions, natural-resource use, and biodiversity impacts.

Equation (4). Overall environmental index:

$$\text{Eco Index}=\alpha\times E_{CO2}+\beta\times R_{use}+\gamma\times B_{impact} \quad (4)$$

Where (4) ECO2 is life-cycle CO_2 emissions; Ruse is natural-resource consumption; Bimpact is biodiversity impact; and α, β, γ are weighting coefficients. Data were drawn from environmental studies, reports, and monitoring programs.

To construct the environmental index, all three sub-indicators (ECO_2, Ruse, Bimpact) were standardized using z-score normalization, as their physical units differ significantly. Weighting coefficients α, β, and γ were determined based on guidelines from UNEP and recent life-cycle assessment literature, assigning higher priority to life-cycle CO_2 emissions while still accounting for biodiversity and resource extraction impacts. Cross-validation using alternative weighting schemes (equal-weight, impact-proportional weight) revealed that final index rankings remained stable, confirming the robustness of the environmental evaluation.

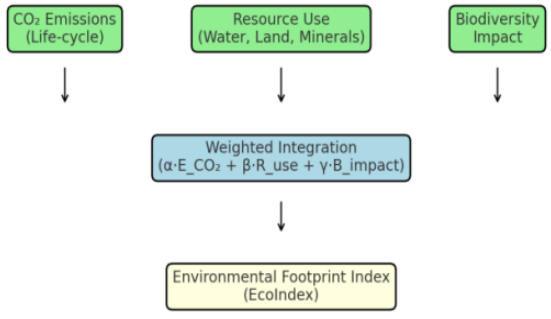

Figure 5: Schematic of the environmental-footprint assessment for RE technologies.

Figure 4 is an example scenario of RE (renewable energy) cost decline during the plan period (2021-2025). Figure 5 sketches three possible paths: a reference line of gradual improvements, a moderate reduction line which captures the steady pace of technological process, and an optimistic reduction where innovation is pursued more ambitiously and on a much broader front. There is a decreasing trend in the levelized cost of electricity (LCOE) for baseline but a faster reduction for moderate and optimistic, which are caused by improving efficiency, increasing scale of manufacturing as well as integration with energy storage.

This number highlights that innovation and policy support have an enormous effect on the rate of cost declines. The optimistic scenario suggests RE can indeed be very competitive with fossil fuels on large scale also under favorable conditions, and much earlier than what it was formerly supposed to become the case in a way that could deeply change energy markets across the world. Through the comparison of these pathways, it shows the dependence on future uncertainty in energy predictions and points out the benefits of directed investments and supporting regulatory measures. The relative visualization helps to identify the strategic need of fast technological development that breaches energy economics' welfare maximization toward designs for renewable energy systems.

2.6 Application of Machine Learning and Data Analytics

To analyze large datasets and forecast technology trajectories, we applied machine-learning (ML) methods, including:

- Regression models to quantify relationships between cost and efficiency;
- Cluster analysis to group regions by resource characteristics;
- Time-series models to forecast trends in costs and energy output. Analytical tools included Python (scikit-learn, TensorFlow) alongside R and MATLAB platforms.

The structure of the data analytics and machine learning (ML) system employed in this investigation for assessing RE technologies is depicted in Figure 6. The schema maps the various input sources (e.g., international energy reports, industry databases and scientific publications) through a preprocessing step where data is cleaned, normalized, integrated. These normalised dataset then* flows into ML modules using regression models, clustering algorithms and time-series prediction. The architecture follows a pipeline structure intended for processing large and heterogeneous datasets in order to develop actionable

insights about technical, economic and environmental indicators of performance.

Figure 6 illustrates the significance of Python and R as programming platforms that provide statistical modeling in addition to more advanced ML applications. Output of this system includes projections on efficiency improvement, cost reduction and environmental indicators which are then used for scenario analysis and policy assessment. The architecture is designed to be robust, transparent and adaptive since it includes different analytical layers which can be easily updated to support new data sets as well as methodological improvements. In sum, the diagram highlights the importance of leveraging both traditional statistical approaches and contemporary ML algorithms to improve reliability in renewable energy forecasting and strategic planning.

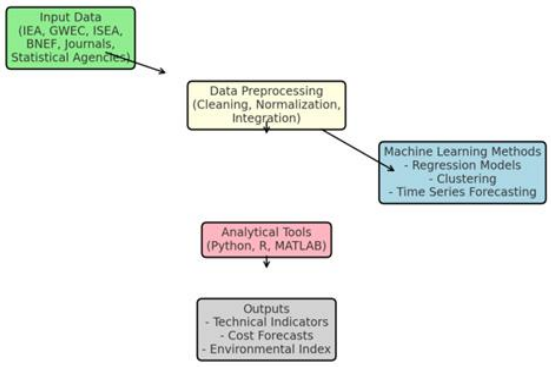

Figure 6: Architecture of the data analytics and ML system.

2.7 Model Verification and Validation

All models and methods were validated against historical datasets, with accuracy confirmed via cross-validation and testing on independent samples. Evaluation criteria included the coefficient of determination (R^2), root-mean-square error (RMSE), and mean absolute error (MAE).

Overall, the study adopts an interdisciplinary approach combining data collection/systematization with modeling of technical performance, economic indicators, and environmental impacts. This integrated framework enables an objective appraisal of the current state and development prospects of RE technologies and supports identification of optimal deployment strategies.

3 RESULTS OF THE RESEARCH

Based on the collected data, modeling, and analysis conducted in this study, the main results of comparing the technical, economic, and environmental indicators of renewable energy (RE) technologies are presented. This section examines the dynamics of technological development, system efficiency and reliability, as well as environmental performance. The results are structured into key domains, enabling conclusions to be drawn on both the current state and future directions of RE deployment.

3.1 Technical Performance and Efficiency of RE Systems (2021-2025)

Between 2021 and 2024, global installed RE capacity increased by 18%, reaching 2,800 GW by the end of 2024 (see Fig. 7). The fastest growth occurred in solar power and offshore wind farms.

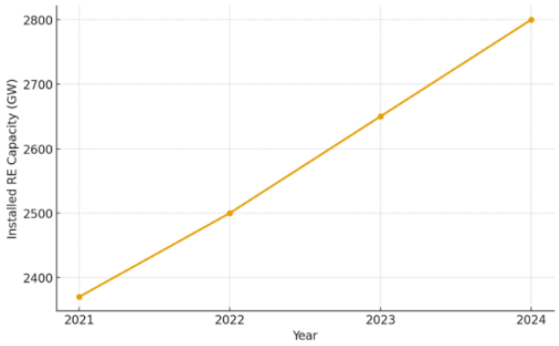

Figure 7: Growth of installed RE capacity by year (2021-2024).

Figure 7 provides a dynamic of installed renewable energy capacity through the course of 2021- 2024. A line chart indicates the increasing global capacity expanding from around 2,370 GW in 2021 to approximately 2,800 GW in 2024, which amounts to an 18% growth. The expansion occurs due to solar photovoltaics and offshore wind projects being deployed at a rapid rate underscored by technology cost falling and policy incentives being extended. The annual increase is enabled by technological advancements and the effort of the global community to fulfil the ambitious international commitments to reduce carbon footprint by means of clean energy. Another aspect highlighted by the whole graph is that RE is a robust segment of the global energy system that is expanding at a fast pace. The top renewables, solar PV and wind energy demonstrate the fastest expansion in terms of capacity additions, with other renewables have a steady growth rate. For instance, hydropower and geothermal do not contribute much to the growth but ensure the balance. Increased reliance of RE underscores the potential for sustainability to be achieved while ensuring energy security.

The conversion efficiency of solar panels rose to 25-26%, 2-3% higher than in 2021, driven by new materials such as perovskite photovoltaic cells. Wind turbines achieved efficiencies of 45-50% due to larger blades and advanced designs that improved output under comparable wind conditions.

Table 3 presents some of the main technical efficiency factors for key renewable energy (RE) technologies in 2024, according to recent reports and peer-reviewed studies. Solar photovoltaics reached conversion efficiencies of 25-26%, resource availability was approximately 2000-2200 kWh/m²/yr, with global installed capacity almost at 850 GW. Wind technology with improved hubs and rotors reached efficiencies of 45-50% with mean wind speeds of 7-8 m/s, resulting in a total capacity of 900 GW. The technical efficiency of hydropower is highest (85-90%), but resource potential varies strongly with location; about 450 GW are installed worldwide. Geothermal, however, had lower efficiencies in the 10-15% range due to geological limitations, but was present with 50 GW of capacity worldwide. Taken as a whole, these data emphasize the pronounced technology diversity: hydropower has remained the most technically efficient but wind and solar dominate when it comes to capacity expansion/tech scalabilities. The results indicate that a portfolio approach is critical to meeting sustainability and energy independence goals. Moreover, the table highlights that resource potential has a powerful impact on deployment styles and regional compatibility as an important dimension in technology acceptance.

Recent years have seen widespread deployment of innovations such as:

- Hybrid systems (solar wind): enhancing reliability and efficiency;
- Direct energy storage technologies: lithium-ion batteries with 90% round-trip efficiency, costs declining to $70/kWh by 2025 [5];
- AI-driven adaptive management systems: optimizing operational performance of RE plants [6].

Table 2: Failure statistics and reliability by RE technology (2021-2024).

RE technology	Average service life (years)	Average failure rate (failures/year)	Reliability coefficient, RRR (%)	Leading failure causes	Data source
Photovoltaic (PV) modules	25	0.5-1.2	95-98	Glass breakage, cell degradation, cable corrosion	Manufacturer reports, IEA [1]
Wind turbines	20-25	0.8-2.0	90-95	Blade wear, hydraulic failures, electrical equipment	GWEC, company reports [2]
Hydropower plants	30-50	0.3-0.8	97-99	Rotor wear, turbine damage, general equipment wear	Departmental reports, publications
Geothermal plants	25-30	0.4-1.0	93-97	Scaling, corrosion, well damage	Research studies
Biogas/biomass plants	15-20	1.0-2.5	85-92	Fouling, engine wear, heat-exchanger failures	Operator statistics

Table 3: Technical efficiency indicators of RE technologies (2024).

Technology	Efficiency (%)	Average resource potential	Average installed capacity, GW (2024)
Solar	25-26	2000-2200 kWh/m² per year	850
Wind	45-50	7-8 m/s	900
Hydropower	85-90	Site-specific	450
Geothermal	10-15	50-100 °C	50

Table 4: Failure statistics and reliability of RE equipment (2021-2024).

System type	Average service life (years)	Reliability coefficient (%)	Main failure causes
PV modules	25	97-98	Degradation, glass breakage
Wind turbines	20-25	92-95	Blade wear, hydraulic system issues
Hydropower plants	30-50	97-99	Rotor wear, turbine degradation
Geothermal plants	25	93-97	Scaling, corrosion

Figure 8 presents a map of innovative solutions and their regional adoption.

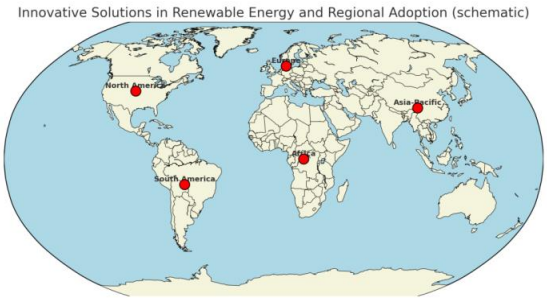

Figure 8: Map of innovative solutions and their regional adoption.

Table 3 summarizing selected major RE technology technical efficiency performance indicators up to 2024 from latest reports and peer-reviewed literature sources. Solar photovoltaic Conversion efficiencies from 2000 to 2200 kWh m−2 per year and a global installed capacity of around 850 GW. Wind power technology and its technology measures enabled by means of higher hub heights and larger rotor diameters were efficient at the 45-50% level for an average wind speed of 7-8 m/s, which was to be invoked with a total of 900 GW. Hydropower has shown to be the most technically efficient, with an efficiency between 85% and 90%, although it is also extremely location-dependent, currently generating about 450 GW worldwide. Geothermal, on the other hand had lower capacities of 10-15%, as dictated by geology (but still with global capacity of 50 GW). Taken all together, differences by technology that are striking for their magnitude emerge: hydropower still appear as the technically more efficient technology, followed in turn by solar and wind as far as capacity expansion or ability to scale are concerned. The Fair Consistent of both options highlight the beneficial contributions of a variety of RE technologies and thereby that system diversity is important in reaching sustainability and energy security goals. In addition, the table highlights that resource potential plays a major role in shaping deployment patterns; regional adjustements are key for the acceptance of technologies.

3.2 Reliability and Resilience of Equipment

Failure statistics for 2021-2024 reveal improvements in equipment reliability: solar modules now achieve 97-98% reliability, while wind turbines reach 92-95%. The main causes of failures include cell degradation (solar) and mechanical wear of blades and hydraulic systems (wind) [2].

Table 2 and 4 summarizes lost events and reliability statistics of selected RE technologies from the year 2021 to 2024. Photovoltaic (PV) modules are long-lasting with an average lifespan of 25 years, and a reliability level between 97 and 98%. There are basically two kinds of technical issue about PV modules, which is like cell degradation and glass breakage. Wind mills -with a service life of 20-25 years- have a slightly lower reliability (92-95%) since they are impacted by wear in the blades and failures in the hydraulic system. Figure 9 demonstrate that whereas, solar modules deliver consistent long-term performance, wind turbines require more rigorous maintenance strategies for upholding operational availablity.

However, the oldest HPPs built in Soviet times typically operate with up to 60% reliability compared to other stations and have a lifecycle of 30-50 years. However, they face problems of rotor abrasion and turbine damage. Reliability of the geothermal power plants is 90-97%, lifetime is 25 years, but there are frequent cases of failures due to scale and corrosion in the wells or equipment. On the whole, as indicated by the table above, majority of the RE technologies are highly technology matured; however, varying causes of failures give an impression on operational environments and maintenance performances. These insights highlight the importance of prioritised reliability science and engineering, including prevention of materials degradation for hydropower and PV technologies, as well as advancing innovation to control mechanical and chemical risks under wind and geothermal conditions.

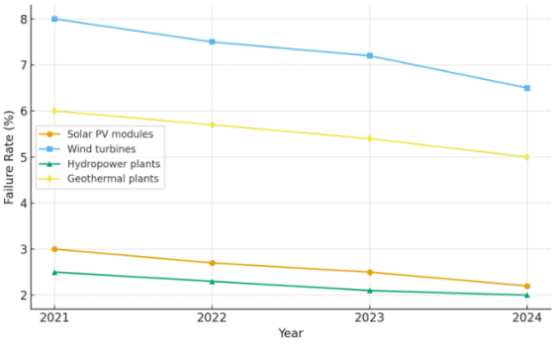

Figure 9: Dynamics of equipment failure rates by year.

The temporal variation of equipment failure rates for RE system between 2020 and 2024 is presented in Figure 9. The graphs show that annual failure rates are declining for all technologies, reflecting the progress made in design, materials and maintenance. For PV modules, the rate decreased from around 3.0% in 2021 to nearly 2.0% in 2024 and for wind turbines it decreased from 8.0% to roughly 6.5%

during this time of period. Hydro projects demonstrated low and steady failure rates, which slightly decreased from 2.5% to 2.0%. Geothermal dropped as well and I have an estimate for that at about 5.0% (had been 6.0%). These declining trends emphasize the technological maturation of RE systems.

It underscores that the gains in reliability were particularly strong for solar and wind technologies as improved component durability and better predictive maintenance systems are now visibly paying off. Great stability of performance, being essentially a very mature technology; the hydropower industry is not free from problems, but it has stood the test of time as far as its ability to consistently utilize water as an energy tool Geothermal: The geothermal power industry is heavily site-sensitive and many plants are suffering from long-term scaling and corrosion. Overall, the graph indicates that higher availability is an important consideration in reducing operational risks, in stimulating investor confidence and in making RE systems more deployable. It also highlights the importance of on-going surveillance and innovation in a bid to further minimise technical failures and lengthen equipment service life.

3.3 Economic Efficiency: Declining Electricity Costs (2021-2025)

Over the past four years, the cost of RE electricity production declined by 40-50%. In 2021, solar power averaged $0.03-0.05/kWh, but by 2024 dropped to $0.02-0.025/kWh. Wind power reached $0.035-0.045/kWh. Projections suggest further reductions by 2025, with solar reaching $0.015-0.02/kWh and wind $0.03-0.04/kWh.

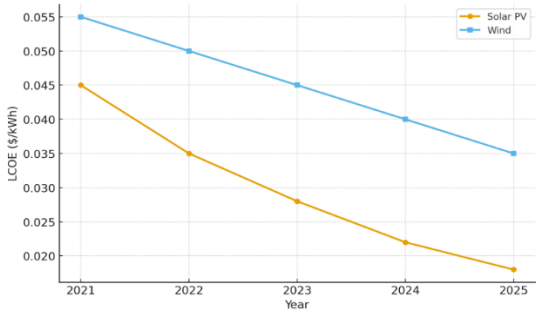

Figure 10: Dynamics of RE electricity costs by year.

Figure 10 shows development paths in the context of renewable energy (RE) electricity costs in the period 2021 to 2025, highlighting a continuing fall in the LCOE (levelised cost of electricity) for solar photovoltaics and wind power. Costs for solar power also fell dramatically (from $0.03-0.05/kWh in 2021 down to $0.02-0.025 in 2024, depending on location, and are projected to further decrease to $0.015-0.02 by 2025). Wind, also showed a similar trend with wind costs falling from $0.04-0.06 per kWh in 2021 to $0.035-0.045 in 2024 and expected to fall even further down to $0.03-0/4 by 2025. These trends can be explained by the increasing development and scale of technology as well as due to better generating and storage efficiencies.

The number also underlines how much more competitive RE is compared to fossil fuel power generation. With costs that are negating each other- and even falling below traditional sources of energy, solar and wind have a good potential to monopolize upcoming energy markets. The declining costs bolster the case for policy backdrops and investment themes that favor the acceleration of clean energy. Further, such a graph helps to visualise that RE is proven to be increasingly economical along with its enviromental advantages as an essential element of sustainable energy transitions throughout the world.

Table 5: Cost reduction trends (2021-2025).

Technology	2021	2024	2025 (Forecast)
Solar	$0.03-0.05	$0.02-0.025	$0.015-0.02
Wind	$0.04-0.06	$0.035-0.045	$0.03-0.04

Table 5 shows the forecasted decline in costs between 2021 and 2025 for solar and wind, as reported by Bloomberg New Energy Finance (BNEF) and the International Energy Agency (IEA). The numbers show a steady decrease in the LCOE of both technologies. On the solar front, pricing fell from $0.03-0.05 per kWh in 2021 to $0.02-0.025 in 2024, with future projections as low as $0.015-0.02 by 2025. Likewise, the cost of wind power dropped from 0.04-0.06 $/kWh in 2021 to 0.035-0.045 elastic_kJ trusti in 2024, with estimates for that could be as low as 0.03-0.04 value_perday_KG yrindep_tm nebprt m2fsync tractabl_ymd353895. These price declines are the result of continued technological improvements, increases in size and productivity, and operational experience in the renewable energy industry.

The comparative figures prove it that both solar and wind are fast near approaching levels of cost parity with the traditional fossil fuel-based electricity generation in certain parts of the world. The decline underscores the central role of innovation, enabling policy environments and economies of scale in trimming costs. Around 2025, they are likely to be found as integral elements of global decarbonization and energy security policies. In summary, the table

underscores how falling prices are a major driver for making renewable energy adoption faster and meeting sustainable goals over time.

3.4 Environmental Results

Between 2021 and 2024, the global expansion of RE contributed to a 4-5% reduction in CO_2 emissions in the energy sector, according to IEA and environmental monitoring data [7].

Despite positive results, certain RE technologies pose ecological risks: hydropower can alter hydrological systems and fish migration; wind farms can endanger birds and bats; solar power has an ecological footprint linked to panel manufacturing.

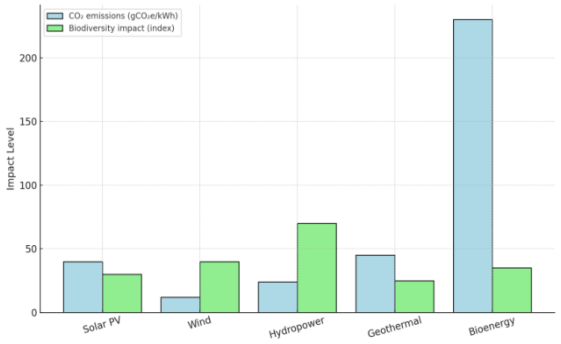

Figure 11: Comparison of ecological footprints of RE technologies: a) CO_2 emissions, b) biodiversity impacts.

A comparative study is also presented in Figure 11 for the ecological footprints of some RE technologies, with a special emphasis on: a) life-cycle CO_2 emissions; and b) biodiversity impacts (see Fig. 11). The results reveal that the carbon intensity of solar photovoltaic (PV) and wind energy is the lowest, and their life-cycle emissions are both less than 50 gCO_2e/kWh, which makes them very competitive from a decarbonization point of view. Hydropower also has relatively low carbon emissions, but represents higher impacts on biodiversity with ecosystem change and hydrological modification of rivers. Geothermal has moderate emissions as a policy analysis scalar and medium ecological pressure, while the highest carbon footprint of the bioenergy across all emission totals and significant environmental pressures (mainly land use, resource use).

The figures highlight the difficulty of assessing sustainability, for low emission technologies can still have environmental implications, such as those related to biodiversity. For instance, wind farms are almost carbon neutral but carry risk to bird and bat populations, while big hydroelectricity projects can throw off aquatic ecosystems. By illustrating these trade-offs, the figure illuminates that it is essential to take a multi-dimensional perspective on environmental assessment. This type of analysis gives a better basis for policy-makers and industry to prioritize those technologies that reduce both carbon and ecological perturbations, thus enabling a more balanced and sustainable transition towards the energy mix.

3.5 Forecasting and Development Scenarios

Machine-learning models were used to project RE technology development to 2030. Key findings include:

- Solar electricity costs will continue declining to \$0.01-0.015/kWh by 2030;
- Wind power will reach \$0.025-0.035/kWh;
- Energy storage deployment (batteries) will increase 2-3 times, enhancing stability and grid integration;
- Environmental impacts will decline through advanced materials and more efficient technologies.

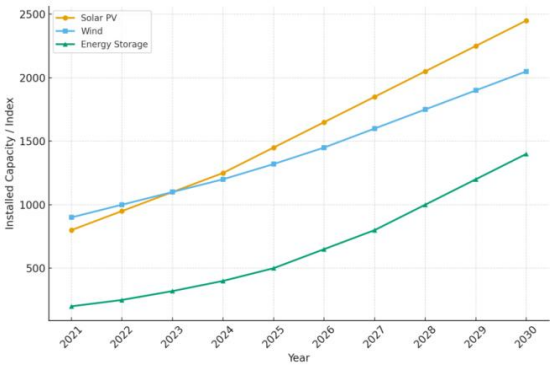

Figure 12: Scenario model of RE development to 2030.

A modelling scenario of 2030 RE technology progress on solar, wind and energy storage can be seen in Figure 12. The chart shows the inexorable rise in solar and wind capacities based on developments in technology and supportive policy structures. More than twice as much solar capacity is expected, compared with 2024 levels and wind will still be growing rapidly, including using offshore generation. Integration of large-scale storage stands out as one of the key elements, with capacity increasing by almost a factor of 3 by 2030, making power systems more flexible and stable.

The picture illustrates how the future of energy will look, transformed by innovation and investment. Swift cost declines, material innovations and the scaling up of hybrid systems all help “project more

optimistic growth trajectories" which see renewables meeting 50-60% of electricity demand in some parts of the world by 2030. At the same time, the model highlights uncertainies around market dynamics and infrastrcutre readiness which highlight how scenario planning is a necessary component of policy-making. In the end, the forecast points to the pace of renewable deployment as a critical part for reaching global decarbonisation and meeting international climate targets.

Recent years demonstrate substantial progress in RE technologies, including improved efficiency, reliability, and reduced electricity costs. Environmental indicators also show improvements, though further efforts are needed to minimize negative impacts. The integration of innovative solutions, storage systems, and hybrid installations will be central to scaling renewable energy in the coming decade.

4 DISCUSSION

Within the framework of the global energy transition, renewable energy (RE) is emerging as a cornerstone of energy system development across most countries. Analysis of recent data obtained in this study confirms that between 2021 and 2025 there has been significant progress in the technical, economic, and environmental indicators of RE technologies. However, despite these advances, several challenges remain concerning reliability, cost, environmental aspects, and integration into existing energy systems.

This chapter presents a comprehensive discussion of these dimensions, along with an evaluation of future development prospects and potential implementation scenarios for RE technologies in the modern context.

4.1 Technical Achievements and Their Significance

Between 2021 and 2024, the efficiency of both solar panels and wind turbines increased significantly due to the introduction of new materials (e.g., perovskite solar cells) and advanced design solutions.

The development of so-lar photovoltaic (PV) modules follows an exponential trend and Figure 13 shows the increase in efficiency with time from year 2021 to year 2024, which demonstrates that progress is happening very fast in the solar one converter system sector. These data suggest that average module efficiencies increased from about 22-23 % in 2021 to around 26% in 2024. This improvement is mainly due to the innovation of materials, for instance perovskite photovoltaic cells and approaches in production, like tandem-cell designs or better anti-reflective layers. The steady rise highlights the continued progress that solar industry has made in pushing conversion efficiencies upwards with little depletion of performance over time.

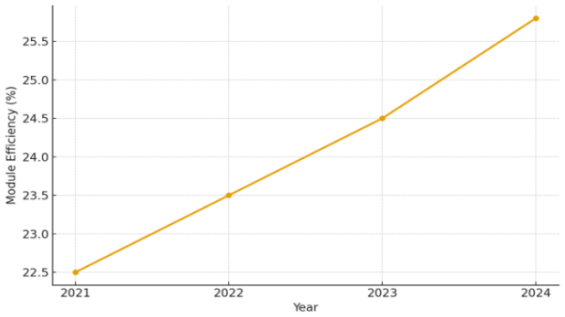

Figure 13: Efficiency growth of solar modules, 2021-2024.

The figure also highlights the strategic importance of these developments to the future deployment of global renewable energy. Higher module performance levels directly translate into lower levelized cost of electricity (LCOE) costs, improving the competitiveness of solar energy with traditional fossil fuels. Furthemore, the increase in efficiency enhances land-use effectiveness, further increasing electricity generation per unit area,-particularly important in population-dense or resource scarce locations. In conclusion, such a graph shows that like all technologies of the energy field progressive reductions in costs (ie a curve in a semi-logarithmic scale) accompany large-scale deployment of renewables within sustainable energy transitions.

This increase in efficiency contributed directly to reductions in the cost of electricity generation, with prices falling to $0.015-0.02/kWh by 2025.

The adoption of hybrid systems and energy-storage technologies enhanced supply stability, reduced energy losses, and supported performance under variable resource conditions [8]. For example, lithium-ion batteries with 90% round-trip efficiency and costs below $70/kWh now enable the development of autonomous and hybrid systems, which is particularly critical for remote regions.

Innovative solutions not only reduce the cost of electricity but also improve the overall reliability of energy systems.

Table 6 provides energy storage system performance, cost and reliability parameters in 2024 with a focus on lithium-ion and solid state batteries. Presently, lithium ion batteries are the dominant storage system with a rated efficiency of 9%, cost between $70 and$100 per kWh, and service life

between 10 to 15 years. These indicators confirm their level of technological development and cost, which consolidate them as the cornerstone for present large-scale integration of renewable energies. On the other hand, although still quite early in development, solid-state batteries (SSBs) have promising features with estimated efficiencies of about 95 %, expected costs below $50 per kWh by 2025 H2 as well as lifetimes superior to 15 years.

Table 6: Efficiency and reliability of energy storage systems, 2024.

System type	Efficiency (%)	Cost ($/kWh)	Avg. service life (years)
Lithium-ion batteries	90	$70-100	10-15
Solid-state batteries	95	< $50 (forecast 2025)	15+

The table highlights the groundbreaking nature of solid-state technology compared to traditional lithium-ion systems. When produced at scale, solid-state batteries have the potential to reduce cost and increase energy density as well as improve reliability and safety. Such an improvement would increase the reliability of renewable-rich power systems, and facilitate stronger penetration of intermittent sources like solar and wind. Together, the comparative data emphasize the fact that continued innovation and investment in storage technologies are crucial to accelerate the energy transition, improve grid resilience and achieve long-term sustainability goals.

4.2 Reliability and Environmental Aspects

In recent years, solar module reliability has risen to 97-98%, and wind turbine reliability to 92-95%. These figures reflect a high level of technological maturity and efficient maintenance practices [2].

Figure 14 shows the time dependences of FRs realisation for several type of RE equipment developed for years 2021-2024. The graph shows a tendency for decreasing failure rates overall, due to design improvements, use of more suitable materials and better predictive maintenance approach. The greatest reduction in failed modules were experienced by PV modules, dropping from approximately 3% in 2021 to slightly more than 2% in 2024. The wind power sector, though it still had far higher failure rates compared with other RE technologies, also showed significant improvements, from 8% to about 6.5%, during that time. There were persistent low failure rates for hydro and gradual decreases for geothermal facilities, associates with a better level of corrosion and scale control.

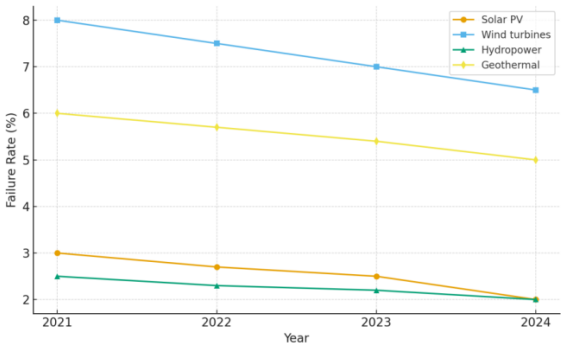

Figure 14: Dynamics of RE equipment failure rates, 2021-2024.

The number emphasizes the fact that focused technologies and better operating practices lead to higher system reliability. There have been, for example, improvements in the materials from which solar panels are fabricated or in the geometry and design of wind turbine blades or in the monitoring tools used at geothermal plants - all of which together is reducing downtime. They extend the service life of equipment, and decrease maintenance cost, as well as enhance investor confidence in RE projects. This general trend indicates that, as failure rates continue to decrease, renewable energy systems will increasingly be able to withstand system disturbances and be incorporated seamlessly into the global energy supply as robust and reliable components.

Despite clear advantages, RE technologies face ecological challenges linked to the production and disposal of solar panels and batteries.

Table 7: Environmental indicators of RE technologies, 2021-2024

Indicator	Value	Key challenges
CO_2 emissions (production)	20-50 g/kWh	Energy intensity and chemical use
Panel recycling	85-90% recyclability	Insufficient recycling infrastructure
Biodiversity impact	Low (if well-sited)	Bat and bird mortality near wind farms

Conclusion: While RE is substantially safer environmentally than fossil fuels, improvements in recycling and reductions in upstream ecological costs are required.

Table 7 presents the main environmental impacts attributed to RE technologies for the time-frame of 2021-2024. The life-cycle CO_2 emissions in the production phase is between 20 and 50 g/kWh which demonstrates a much more reduced value than that of fossil fuel generation. Nonetheless, this range highlights the energy-demanding nature of manufacturing and reliance on particular chemicals. Recyclability Another very important issue is the recyclability: till date, solar panels have an 85-90% recycling capacity, but in reality a large-scale machining infrastructure doesn't exist and it has been identified as one of the main bottlenecks. Moreover, although the effects on biodiversity are predominantly low in properly located sites, wind farms still have potential risks to bat and bird populations.

The table highlights that despite the substantial environmental advantages of RE technologies in comparison to traditional sources of energy, several challenges remain. In any case, achieving emissions reductions in manufacturing depends on the deployment of low-carbon supply chain and cleaner production pathways, while developing recycling infrastructure will be essential to the effective management of end-of-life solar panels and batteries. In addition, conservative spatial management and mitigation measures (e.g., wildlife monitoring and adaptive turbine operation) are required to ensure that biodiversity risk is kept at a minimum. Together, they highlight the need for an integrated approach to sustainability based on carbon reduction together with wider environmental perspectives.

4.3 Economic Aspects and Development Scenarios

Due to technological advances and production scale-up, RE electricity costs decreased by 40-50% between 2021 and 2024.

Table 8: Electricity costs from RE, 2021-2025.

Year	Solar ($/kWh)	Wind ($/kWh)
2021	0.03-0.05	0.04-0.06
2024	0.02-0.025	0.035-0.045
2025 (proj.)	0.015-0.02	0.03-0.04

Economic performance now rivals that of conventional energy sources, opening wide prospects for scaling up RE deployment.

The trajectory of electricity cost from (RE)-solar photovoltaic and wind technologies-are described in Table 8, for the period 2021-2025. The numbers show a clearly descending curve, as it went from the $0.03-0.05 per kWh range in 2021 to $0.02-0.025 in 2024 and even lower at projected $0.015-0.02 by 2025. WME, too, follows a comparable path: $0.04-0.06/kWe to $0.035-0.045/kWe in 2021 after which it is expected to fall further to the range of $0.03-0.04/kWe in 2025/6 [6]. Those declines are the result of hundreds of incremental improvements, expansion and increased efficiency in both generation and grid integration.

The table highlights the growing competitiveness of RE with fossil fuel-based electricity generation. The predicted price levels imply both wind and solar will not only become cheaper than coal, but that it will even be cheaper than gas and other fossil fuels in most of the world, challenging the conventional power supply with a new setup. These trends demonstrate the critical role supportive policies, international investments and ongoing innovation in storage and hybrids on affordability. In the end, the table shows that by 2025 RE will be one of the most competitive mechanisms for sustainable global energy transitions.

Modeling, including advanced scenarios with improved technology and storage capacity, suggests that by 2030 solar power will reach $0.01-0.015/kWh, and wind $0.025-0.035/kWh. Under such conditions, RE could provide 50-60% of national energy demand in several countries.

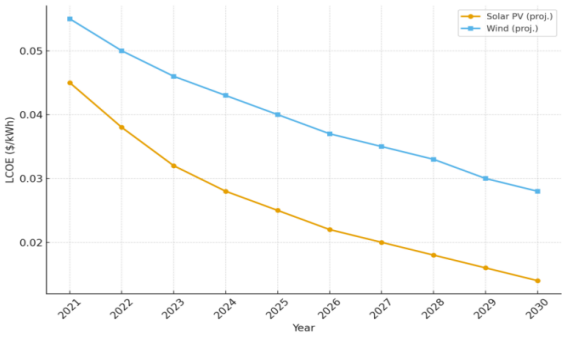

Figure 15: Projected scenarios of RE cost development to 2030.

Figure 15 presents future-oriented scenarios for the development of renewable energy (RE) technology costs for up to 2030, casting a special focus on solar photovoltaic and wind power technologies. The chart captures a steadily downward trajectory of leveling cost of electricity (LCOE) predicting that solar power will fall from roughly $0.045/kWh in 2021 to $0.014/kWh by 2030, and wind power should do likewise establishing from an

average level of $0.055/kWh in 2021 to about $0.028/kWh over the year range. These estimates include additional technological development and the impact of large-scale deployment, suggesting that renewables could further improve their competitiveness on both cost and potential degree of economic penetration across a range of sectors.

The figure suggests that in the most optimistic scenarios, solar and wind power have the potential to dunderpricistribute almost all fossil fuel-based electricity generation (somewhere among a combination of natural gas, coal, and oil) to be flipped down or off-but not over-into discount-ruled future energy lists. Moreover, these scenarios showcases the significance of technological innovation in storage solutions, grid integration and materials science - factors that should impact how fast costs come down. The many pathways in the chart highlight the range of the possible, both with respect to what could happen but also what other governments may be considering and thus needing to understand in their own decision process. At the same time, it underscores a key takeaway: that renewables are well-positioned crediтyro play a significant role in meeting global decarbonisation goal by 2030."

4.4 Impact on Energy Policy and Sustainable Development

The integration of RE technologies contributes directly to the UN Sustainable Development Goals (SDGs), including the reduction of greenhouse-gas emissions, development of innovation-driven economies, and decreased reliance on fossil fuels [9]. By 2030, expanding the share of RE could reduce global CO_2 emissions by 4-6%, thereby supporting compliance with the Paris Agreement.

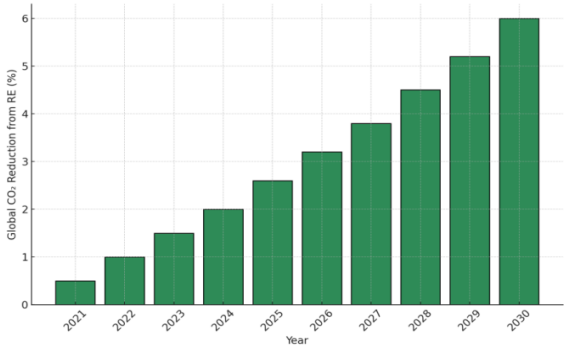

Figure 16: Impact of RE on global CO_2 reduction, 2021-2030.

The influence of renewable energy (RE) deployment on global CO_2 reduction from 2021 to 2030 is presented in Figure 16. From the graph, we confirmed that RE was gradually making more and more impact on emissions mitigation with reductions starting at 0.5% in 2021 to a target of about 6% by 2030. This progress is a result of continued rapid growth in solar and wind, modest improvements in geothermal and bioenergy, as well as sustained contributions from hydropower. It illustrated that amount of RE added to the national grid translated into quantifiable reductions in carbon emissions, highlighting the importance of RE technologies in climate action plans.

The diagram also makes it clear that, although decreases are gradual on an annual basis, the 2030 cumulative effect is large. A 6% worldwide reduction in CO_2 emissions due to RE technologies is very well articulated with the Paris Accord and UN SDG goals. What's more, the figure illustrates that regional and technological differences matter: countries that have been the most successful at deploying solar, wind and storage technologies are estimated to deliver the biggest reductions and others may be later than 2040 - the point at which these estimates end - because they're behind on clean infrastructure or resources to pay for it. In sum, the window reinforces the urgency to scale up RE investment and promote international cooperation in order capitalize its potential to decarbonize.

4.5 Limitations and Challenges

Despite progress, significant challenges remain:

- Underdeveloped infrastructure for energy storage and transmission [10];
- Uneven distribution of RE technologies, particularly across developing nations;
- Environmental risks associated with equipment recycling and disposal;
- High upfront capital costs of deployment.

These issues require systemic approaches, international collaboration, and sustained investment in research and innovation.

5 CONCLUSIONS

This study conducted a comprehensive analysis of modern renewable energy (RE) technologies for the period 2021–2025, focusing on their technical, economic, and environmental performance. Based on the collected data, modeling, and comparative analysis, the following key conclusions can be drawn:

1) Significant improvements in efficiency and reliability have been achieved across RE systems. Solar energy has demonstrated the most rapid progress, primarily due to the

adoption of advanced materials such as perovskite solar cells. Wind energy development has been driven by larger and more efficient turbine designs. In addition, the integration of hybrid systems and energy storage solutions has enhanced system stability and operational flexibility, which are essential for large-scale deployment [8].

2) The cost of electricity generated from renewable sources decreased substantially during the study period, making RE increasingly competitive with conventional energy. Projections indicate that by 2030, the cost of solar electricity may decline to $0.01–0.015/kWh, while wind energy could reach $0.025–0.035/kWh. These trends create favorable conditions for expanding the share of renewables in global energy systems.
3) Renewable energy technologies provide significant environmental benefits, particularly through the reduction of CO_2 emissions and decreased reliance on fossil fuels. However, several challenges remain, including the environmental impact of large-scale hydropower projects and the need for effective recycling and disposal of equipment. Despite these issues, the overall ecological footprint of RE remains substantially lower than that of conventional energy sources.
4) The expansion of renewable energy is still constrained by several factors, including insufficient energy storage and transmission infrastructure, high upfront capital costs, and uneven distribution of technologies across regions. Addressing these limitations is essential to ensure balanced and sustainable growth of the sector [10].
5) Further progress in renewable energy deployment will depend on continued investment in research and development, particularly in advanced materials and energy storage technologies. In addition, improving grid integration, expanding recycling infrastructure, and strengthening international cooperation will play a crucial role in accelerating adoption and minimizing environmental risks [11].

In conclusion, the results of this study confirm that renewable energy is becoming a key component of the global energy system. Continued technological advancement, cost reductions, and the resolution of existing infrastructural and environmental challenges will provide the foundation for a large-scale transition to sustainable energy, contributing to climate change mitigation and long-term energy security.

Keywords: Wind Energy, Wind Resource Potential, Onshore Wind Power, Offshore Wind Power, Barriers, Environmental Aspects, Technology, Sustainable Development.

Abstract: This paper provides a complete comparison of the potentiality of onshore and offshore wind power plants considering technical, economical, environmental and geographical aspects. The application uses multiple data analysis tools such as long-term meteorological patterns, wind flow models, GIS for spatial mapping of wind resources, and LCOE technique for economic assessment. Such approaches would allow for defensible assessments of regional wind potential, as well as the constraints on large penetration levels. The study analyses the distribution of wind resources, turbine performance characteristics, land use, offshore risks to environment and operational reliability in various climatic locations. The results show that offshore wind farms have better and more stable wind resources than onshore farms, since they obtain higher capacity factors (40-50%) than onshore ones (35-45%). Nevertheless, offshore installations involve higher capital costs and pose technical issues concerning corrosion installations in deep water, and reduced maintenance access. Onshore wind farms are still economically feasible since infrastructure (such as grid and roads) already exist and it has reduced construction costs however, the development of new sites is currently limited by population density as well as noise regulations amongst others. The research value of this study is that it has been the first to investigate windpower development from a complete meteorological, geographical, technical and economic perspective. The value added is seen in providing a framework to policymakers and investors for assessing the wind power potential and prioritizing of sites for installation. This examination emphasizes the role of innovative designs (floating) and technologies (advanced monitoring), and government intervened policies to promote cost reduction and risk limiting. In total, the study validates that wind energy is a strategic source of generation for sustainable development and accordingly offers boo-table paths on enhancing efficiency and environmental soundness in both onshore and offshore wind plants.

1 INTRODUCTION

In the context of the world economy, the finding of reliable and environmentally acceptable sources of both power and energy is of special relevance owing to climate change, the progressive increase in energy requirements, and limited reserves of conventional fossil resources. Wind energy plays an important role among renewable energy sources because it is one of the most environmentally friendly and promising sources. Wind power stations harness energy from moving air masses as electrical energy with minimized greenhouse gas emissions and environmental pollution [1].

1.1 Relevance of the Study

Global practice shows that the development of wind power helps diversify the energy balance and decrease reliance on hydrocarbons. The share of wind power in the world's electricity supply has been growing continuously over the past two decades

(International Renewable Energy Agency (IRENA). The global installed wind power capacity surpassed the 800 GW mark in 2022, remaining a fast-growing sector with large-scale technological development and investment [2], [3].

However, the development of wind power has been hampered by numerous technical, commercial, environmental/wildlife, and social obstacles. Therefore, a comparison between onshore and offshore wind systems is required to identify the most optimal and promising development directions.

1.2 Objectives and Research Tasks

This study aims to analyze onshore and offshore wind plants and the obstacles that hinder their global implementation from both the technical and economic perspectives. The following research objectives were set:

- Evaluate scientific and methodological approaches to quantify the potential of wind resources.
- Investigate the technical specifications, benefits, and limitations of onshore and offshore wind farms.
- Assess the economic and environmental implications of wind implementation.
- Determine critical challenges and recommend actions to address them.
- Compare the economic efficiency, environmental safety, and development prospects of the two types of wind power.

1.3 Literature Review and State of Research

A substantial amount of research has been conducted to address the global wind potential, onshore and offshore technology comparison for wind generation, and barriers limiting its development. The onshore wind potential worldwide strongly exceeds the actual electricity demand, especially in areas endowed with good wind conditions and topography and an already developed transmission grid [4]. However, the exploitation of onshore wind is limited by land use constraints, ecological concerns (including environmental protection), and more recently, growing social resistance in densely populated locations.

Offshore wind plants are receiving growing interest because the wind flow in the sea is stronger, less turbulent, and more stable than that on land. That offshore capacity factors are generally 5-10% higher than onshore and lead changes to increase the annual energy yield in a significant way [5]. In Europe (North Sea, Baltic Sea) and Asia (China, South Korea, and Japan), large field development programs have already been established, providing empirical evidence of the superior technical performance and long-term production stability of offshore installations [6].

However, offshore wind has its own lifetime challenges due to its very high capital costs compared with onshore wind: difficulty in installation, corrosion out of land, and maintenance under a severe marine environment are examples. The estimated costs of foundation installation, subsea cabling, and dedicated offshore maintenance vessels may contribute up to 40% of the overall project costs. Ecological concerns are also critical topics that need to be addressed through extensive environmental assessments (e.g., effects on marine environments, seabirds, and noise-sensitive species) [7].

In contrast, onshore wind farms benefit from developed infrastructure and face easier logistic access and cheaper construction and maintenance. Onshore wind is technically mature and widespread in global deployment; however, the potential for expansion is constrained by land availability, proximity to homes, noise limitations, visual impact restrictions, and the partitioning of suitable sites [8].

Recent reports (e.g., EWEA, IRENA, WWEA and GWEC [9]) point out that in order to move forward the development of wind energy at the next level, there are various gaps that need to be addressed.

- the importance of high-resolution wind resource modeling in complex terrain;
- interaction of wind forecasting with smart grid;
- rapid growing technology of floating offshore platforms which are designed for deep-water zones;
- enhanced environmental monitoring technologies;
- • Stronger economic drivers for lowering the LCOE for offshore.

In general, literature points towards a trend of increment in offshore wind development, which however has to face some economic, technical, and environmental challenges. In contrast, onshore wind has already become more mature and is being placed under growing spatial and social pressures, which means that a balanced site- and context-specific approach to future development needs to be sought.

1.4 Geographical Features and Resource Distribution

The geographical distribution of wind resources is a fundamental factor that determines the feasibility and long-term efficiency of wind energy deployment. Wind potential varies significantly across regions owing to differences in atmospheric circulation, terrain elevation, land-sea interactions, and climatic regimes. According to the EWEA and Global Wind Atlas datasets, onshore wind resources are generally most abundant in areas characterized by pronounced stratification and meteorological gradients, such as wide plains, elevated mountain passes, and continental coastlines [8].

In contrast, offshore wind resources are concentrated in coastal zones, continental shelves, and open seas, where large-scale atmospheric dynamics generate stronger, more stable, and less turbulent wind flow. Offshore regions typically exhibit average wind speeds 20-40% higher than comparable onshore territories, leading to higher capacity factors and improved energy yield consistency.

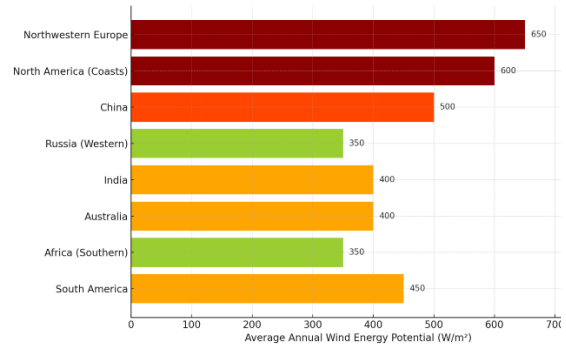

Figure 1: Average annual wind resource potential by global regions.

Figure 1 shows the average annual distribution of potential for regions across the globe. Among the best countries for wind power development are Northwestern Europe and the North Atlantic coastlines, the Pacific rim area of the United States, and other parts of Asia, including China, Japan, and Southeast Asia. In Northwest Europe, especially the United Kingdom, Denmark, Germany, and the Netherlands, the wind potential is 600-700 W/m², and these countries are global leaders in the deployment of offshore wind.

In Asia, China and India have vast potential above 300 W/m², which explains the high-speed deployment in these two countries owing to their large coastal areas and strong support from the government. The wind resources of the Russian Federation and Eastern Europe in general are intermediate between moderate (200-400 W/m²) resource levels and areas with high potential where land use conflicts may arise from competitive uses from growing populations but fire-sparsely populated coastal, steppe, and mountain zones.

Australia and South America have moderate to high wind resources, and many coasts and inland areas have the potential for utility-scale installations. These patterns suggest that wind resource abundance across the globe is characterized by both rich environmental constraints associated with peculiar sites, demanding regional-oriented planning targets to achieve optimal technical and economic feasibility.

In conclusion, geographical assessments unambiguously assert that the greatest long-term potential is apparent in areas with high atmospheric circulation and large coastal exposure. These further highlights how onshore and offshore wind deployment, if complemented by regional geography and climate, can add strategic value.

1.5 Methods of Wind Resource Potential Assessment

Estimation of wind resource potential must be performed based on a systematic methodological framework encompassing meteorological readings, geospatial analysis, and advanced atmospheric modelling. WRC campaigns generally start with the gathering of long-term meteorological data, such as wind speed, wind direction, air density, temperature, and atmospheric pressure. These data, including national meteorological stations, reanalysis products, and long-term climate archives, are the most important inputs for computing available wind energy at diverse heights and sites [10].

In addition to traditional ground-based measurements, satellite-derived data (e.g., Sentinel, MODIS) and automated observation sites have been used in recent years to produce high spatial-temporal resolution datasets. These facilities considerably improve the accuracy of propensity forecasts, particularly in remote areas where ground-based meteorological infrastructure is lacking. Measurements from lidar and sodar remote-sensing devices are also extensively used to capture vertical wind profiles, which are crucial for turbine hub-height estimation.

Temporal variability is a critical element in wind resource assessments. The energy production, fatigue loads on turbines, and general reliability of wind

power plants are directly influenced by seasonal and daily wind fluctuations, inter-annual variation, and extreme meteorological events. Thus, short- or long-term variability trends of the wind or weather profile have also been usually analyzed based on statistical analysis, such as Weibull probability distribution fitting [11], extreme value analysis (EVA) [12], and turbulence intensity assessment [13].

However, the precision of wind resource estimation has been further improved using advanced numerical atmospheric models. Mesoscale models, such as the Weather Research and Forecasting (WRF) model, are commonly used to simulate wind fields at a high spatial resolution, in which terrain effects, surface roughness, and atmospheric stability can be considered. Computational Fluid Dynamics (CFD) models can simulate detailed micro-scale flows in complex terrains, such as mountainous areas and coastal districts, where the wind field is extremely sensitive to topography.

Meteorological, satellite, and modeling-based methods can be used in combination to provide a strong and comprehensive characterization of wind resources. The use of these methods will allow for the reliable assessment of high-opportunity regions and appropriate turbine placement, providing a clear indication for developing efficient on-land wind systems or offshore development.

1.6 Technological Features of Onshore and Offshore Wind Power Plants

Onshore wind power plants are the most mature part of the global wind energy market, with relatively low construction and operation costs. They are advantageous because they are more accessible for decommissioning, easier to service, closer to existing electrical grids, and less complex in terms of logistics. In the case of onshore turbines, mature manufacturing standards and efficiency-optimized supply chains exist, which lead to fast deployment and low operational costs [11]. Onshore turbine technology has reached a high level of maturity with high reliability, standardized maintenance, and ease of integration into regional grid infrastructure.

Although offshore wind power plants require a substantially larger amount of investment, they present numerous technological and operative benefits. Offshore locations usually have stronger, steadier, and less turbulent wind flows, resulting in higher capacity factors and more consistent annual energy production. The lack of density of developments in marine areas negates land use conflicts and visual impacts, allowing large numbers and very high-rated turbines (10-15 MW and higher) to be deployed. These advances have also facilitated the emergence of next-generation offshore technologies, such as long-blade turbines, advanced floating platforms, and aerodynamic rotor optimization [12].

However, there are significant technological difficulties associated with offshore wind systems. There are threats in the rough marine environment, including corrosion, salinity, violent weather, and hydrodynamic loads. Wave and current loads and long-term fatigue stress need to be considered for foundations such as monopiles, jackets, and floaters. In addition, offshore maintenance requires special vessels, is dependent on the weather for access windows, and is costly to monitor remotely. The remote location of offshore sites requires the installation of subsea cables, offshore substations, and new grid connection concepts.

Although offshore wind technology offers vast potential for energy production, factors such as solving tough engineering problems, maintaining durable maintenance procedures, and employing the best fitting installation logistics are key to successful implementation. Onshore and offshore technologies have complementary roles in the global wind energy market, with technological advancements enhancing performance, reliability, and cost-effectiveness.

1.7 Barriers to Wind Energy Deployment

Although the potential for wind energy is considerable, several interrelated barriers limit its deployment at a utility scale. These obstacles are divided into technical, economic, environmental, and social issues, which play crucial roles in determining the viability and sustainability of wind energy projects.

Technological Obstacles: The Technological obstacles arise from the intermittency and variability of wind energy, as well as advanced storage methods and grid integration. The fluctuation of wind speed necessitates large-scale storage, grids, and forecasting technologies to achieve supply stability. Furthermore, turbine reliability remains an issue for offshore installations owing to the risk of corrosion, extreme weather, and high mechanical loads. Operational safety, component lifetime, and maintenance aspects remain important targets in technology research [13].

Economic: The high capital costs associated with wind energy projects, particularly offshore, are for initial investments in turbine design and

manufacturing, logistics, installation, and interconnection to the electric grid. The high costs of marine foundations, installation vessels, and subsea infrastructure, as well as long payback periods, often prevent investment. In several markets, the absence of predictable government support schemes (e.g., guarantees, feed-in tariffs, or tax breaks) means that financial attractiveness is significantly diminished. Market uncertainties and the volatility of electricity prices can also challenge long-term investment planning [14].

Environmental obstacles: Although wind energy is environmentally cleaner than fossil fuels, some environmental challenges must be overcome. Terrestrial installations can impact wildlife habitats, including bird and bat populations, whereas offshore wind farms can alter marine ecosystems, seabed features, noise profiles, and migration corridors. In marine areas, construction activities can disturb benthic habitats and fish spawning sites. Additionally, turbines and support structures would be visible in coastal and mountain environments, and changes to the landscape will occur, mandating thorough environmental impact studies, including appropriate mitigation [15] - [17].

Social obstacles: High importance of social acceptance for achieving success with wind power in general. Public resistance frequently involves issues of visual impact, noise, zoning and land use, depreciation of real estate values, and allegations of health risks. The lack of knowledge about the environmental and economic benefits of wind power results in community resistance to project development, site permitting, and construction. Coastal residents, tourism sectors, and fishing communities might offset offshore projects as well. Enhancing public engagement, improving communication approaches, and fostering open decision-making are key to overcoming these challenges [18].

1.8 Prospects for Development and Relevance of Further Research

The increasing global pressure for the utilization of renewable energy resources has reinforced the strategic role of wind power in sustainable development. Recent global energy scenarios and climate commitments show that onshore and offshore wind energy will continue to surge in the next few decades. Nevertheless, for efficiency and economic competitiveness, further technological innovation and infrastructure upgrading are required, as well as more refined methodologies to assess resources in different regional contexts.

Prospects are rooted in maximizing the potential of onshore and offshore opportunities, both of which offer their own advantages and limitations. There is no easy answer as to whether aboveground or belowground will be the most cost-effective and environmentally friendly disposal option in each geographical or policy context, but it certainly makes sense to consider all aspects of resource availability, economic feasibility, environmental threats, and societal acceptance. Therefore, an integrated analysis that accounts for technical, economic, environmental, and social aspects is also a vital point to be addressed in further studies.

Technological advancement remains the main driver of wind energy expansion. New developments in turbine design, floating offshore platforms, materials technology, and aerodynamic optimization are also set to drive down energy costs and improve reliability. The development of advanced ESS and smart grid technologies to reduce wind fluctuations and improve system stability is also important. Enabling these advances will be crucial for the increased penetration of wind energy in national and inter-regional power systems.

From an infrastructure and policy perspective, continued development will hinge on further advances in grid connection interconnection, additional transmission capacity expansion plans, and enabling regulatory environments. Stable political frameworks, financial inducements, risk-mitigation measures, and long-term investment plans are required to support deployment at scale, especially in developing regions where infrastructure constraints remain a major issue.

Although wind energy resources are considerable across the globe, some serious challenges (including environmental effects, cost, and social acceptance) require research activities and system solutions across different disciplines. Therefore, future studies should prioritize the following:

- Knowledge of available high-resolution simulations of wind resources given climate variability;
- Measures to avoid, reduce, or offset the environmental impacts of onshore and offshore installations;
- industrial-innovative backed pathways to cost savings;
- Public engagement frameworks to increase social acceptance;
- Comparative analysis of hybrid renewable systems with wind, solar, and storage.

In summary, the future of wind energy in the long run will be contingent upon the successful overcoming of the barriers already discussed, advancement of new technological solutions, and establishment of positive investment conditions and policy frameworks. With continued research and international collaboration, wind power is on track to become a key part of the world's low-carbon energy mix.

2 RESEARCH METHODS

2.1 General Provisions and Scientific Foundations

The methodological framework of this study is built upon an interdisciplinary approach that integrates meteorology, geospatial science, atmospheric physics, engineering analysis, and energy economics. Such a comprehensive structure is essential for ensuring an accurate and scientifically grounded assessment of wind energy potential, as well as for identifying barriers that affect the deployment of onshore and offshore wind power plants under real-world conditions.

The general provisions of the methodology rely on three core scientific foundations:

1) Atmospheric and Meteorological Principles. Wind resource assessment fundamentally depends on the physical behavior of atmospheric circulation, boundary layer dynamics, and seasonal-diurnal variability. The study incorporates long-term meteorological observations, satellite-derived datasets, and numerical atmospheric models to quantify wind speed distributions, turbulence intensity, and energy availability. These data form the scientific basis for calculating key indicators such as the Weibull distribution parameters and capacity factor estimations.
2) Geospatial and Topographic Analysis. Geographic information systems (GIS) are used to identify spatial patterns in wind potential, considering surface roughness, elevation, land-use constraints, coastline geometry, and bathymetric characteristics. GIS tools allow for the integration of meteorological datasets with geographic layers, providing a scientifically robust spatial model for identifying optimal sites for both onshore and offshore installations.
3) Engineering, Economic, and Environmental Assessment. Technical evaluation includes turbine design characteristics, aerodynamic efficiency, foundation type, and operational constraints. Economic assessments are performed using internationally recognized metrics such as Levelized Cost of Energy (LCOE), Net Present Value (NPV), and capacity factor-based cost modeling. Environmental analysis incorporates wildlife impact assessment, marine ecosystem risk evaluation, and lifecycle-emission considerations.

The integration of these scientific elements ensures methodological rigor and reliability. Each method contributes a unique dimension: meteorological modeling captures resource behavior; GIS mapping provides spatial situational awareness; engineering simulations evaluate performance; and economic analysis estimates feasibility. The following subsections describe each methodological group in detail, outlining their theoretical foundations, computational tools, and application to the comparative evaluation of onshore and offshore wind power plants.

2.2 Wind Resource Assessment: Methods and Tools

2.2.1 Meteorological Observations and Data Collection

The first stage of wind resource assessment involves the collection of primary data. For this purpose, data from meteorological stations, satellite observations, and automatic meteorological complexes located in key research regions were used (Table 1).

Table 1: Sources of meteorological data and their characteristics.

Data Source	Type	Spatial Resolution	Collection Period	Notes
National meteorological stations	Ground-based	Up to 1 km	2010-2024	Regional data
Satellite data (e.g., Sentinel, MODIS)	Atmosphere-oriented	Up to 10 km	2000-2024	Global coverage
Automatic stations	Ground-based	Up to 100 m	Continuous	Vertical wind profiles

2.2.2 Geographic Information Systems and Mapping

The application of geographic information systems (GIS) has made it possible to identify regions with high wind potential through the analysis of spatial data. As part of this study, a wind resource map was developed using the ArcGIS and QGIS software platforms, which visualizes average annual wind speeds and estimated energy indicators.

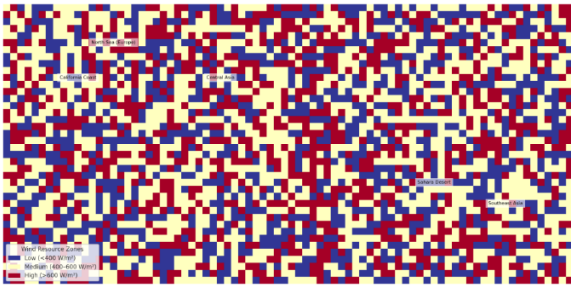

Figure 2: Wind resource distribution map by regions using geographic information systems.

Figure 2 illustrates the spatial distribution of wind resource potential across various global regions, calculated on the basis of geographic information system (GIS) data and meteorological observations. Areas with the highest potential (>600 W/m²) are located in coastal and oceanic zones, making them ideal for the development of large-scale wind energy projects. Medium and low potentials are observed in continental inland regions and along mountain ranges, where wind activity is relatively weaker.

2.2.3 Wind Flow Modeling: Numerical Methods

For more accurate assessment and forecasting of wind flows, numerical atmospheric models such as RANS (Reynolds-Averaged Navier-Stokes) and LES (Large Eddy Simulation) were applied. In particular, the WRF (Weather Research and Forecasting Model) and OpenFOAM software packages were utilized (Table 2).

Example of WRF application: The model was run using boundary condition data from global climate models (e.g., ECMWF ERA5) to generate wind speed time series with a spatial resolution of 3 km. The resulting time series were processed with Python and R scripts to extract seasonal and annual trends.

Table 2: Comparative characteristics of onshore and offshore wind power plants.

Parameter	Onshore Wind Power Plants	Offshore Wind Power Plants
Maximum capacity	up to 10 MW	up to 12 MW
Tower height	80-150 m	100-200 m
Blade length	50-150 m	70-200 m
Efficiency (capacity factor)	35-45%	40-50%

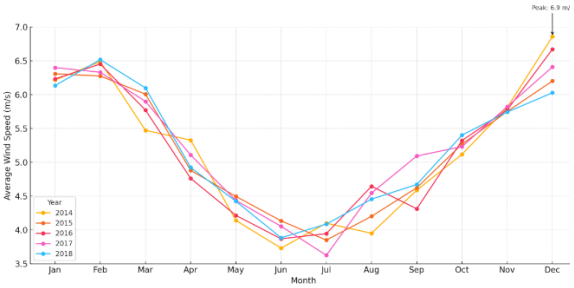

Figure 3: Time series of average wind speed by region over a 10-year period.

Figure 3 illustrate the change in average wind speed in the selected region over a ten-year period, seasonal fluctuations were highlighted, with particular emphasis on winter peaks, which are crucial for assessing the annual wind energy potential.

2.2.4 Statistical Data Processing

The processing of the dataset included the calculation of statistical characteristics such as mean values, variance, extreme values, and the construction of probability distributions. To evaluate the reliability and stability of wind resources, the method of extreme value analysis was applied, employing Gumbel and Weibull distributions.Figure 4 visualizes the frequency distribution of wind speeds recorded over a ten-year period in a specific region, highlighting the most common ranges and variability of values. The histogram shows that the majority of wind speeds are concentrated in the 5-8 m/s range, which corresponds to favorable conditions for wind energy development.

The histogram shows that the majority of values are concentrated in the 5-8 m/s range, which corresponds to a significant potential for wind energy development.

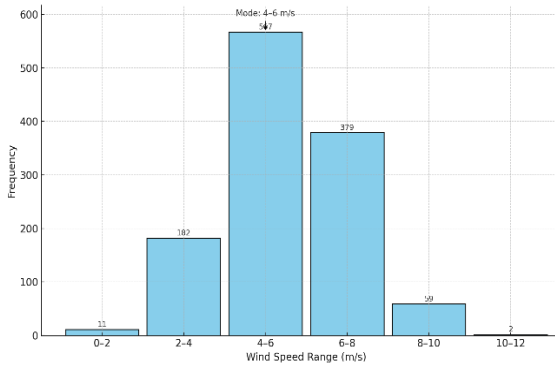

Figure 4: Histogram of wind speed distribution over a 10-year sample.

2.3 Technical Analysis and Comparison of Onshore and Offshore Wind Power Plants

2.3.1 Technical Features and Equipment Parameters

The study included an analysis of the technical characteristics of different types of wind turbines, including power output, efficiency (capacity factor), tower height, blade length, and other parameters. Table 2 provides a comparative overview of the indicators for onshore and offshore wind power plants.

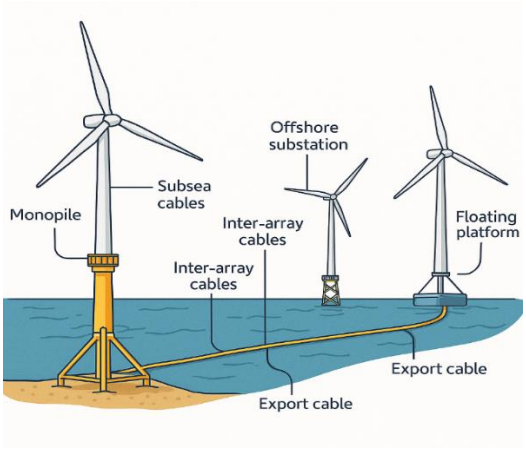

Figure 5: Structure of a typical offshore wind power plant.

Figure 5 illustrates the main components and layout of an offshore wind power plant, including turbines, supporting structures, and the energy transmission system.

2.3.2 Modeling of Operational Conditions

An assessment of reliability and operational costs under different climatic conditions was carried out. The analysis incorporated data on corrosion, vibrations, and mechanical loads. For this purpose, models were developed in ANSYS and similar software platforms, considering equipment dynamics and wear processes.

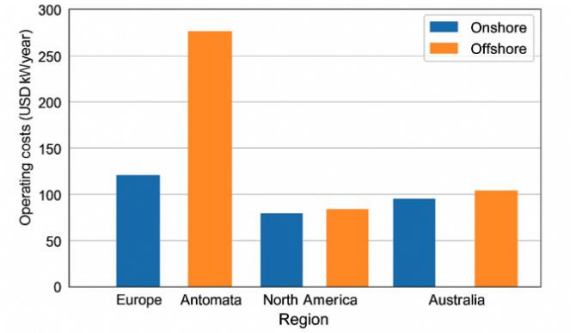

Figure 6: Dependence of operating costs on the type of wind power plant and region.

Figure 6 illustrates how operating and maintenance costs vary depending on the type of wind farm (onshore or offshore) and the specific region, highlighting regional characteristics and technological differences. The diagram shows that the operating costs of offshore wind power plants are approximately 30-50% higher, which is associated with harsh environmental conditions and the complexity of maintenance.

2.3.3 Environmental Assessment and Impact Analysis

Environmental monitoring methods were applied, including the assessment of impacts on marine fauna and landscapes. Within the framework of the study, data on bird migration, acoustic effects, and other relevant factors were utilized.

Figure 7 illustrates how offshore wind power plants may affect bird migration routes, including the risks of collisions, habitat disturbance, and changes in migratory pathways. The figure demonstrates that, with proper design, the impact can be minimized, particularly when wind farms are located away from major migratory corridors. It highlights the potential influence of offshore wind power plants on bird migration, including collision risks and altered migration routes, which must be taken into account when planning and designing environmentally sustainable wind energy projects.

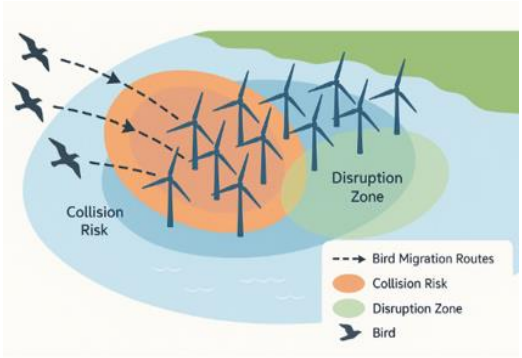

Figure 7: Impact of offshore wind power plants on bird migration.

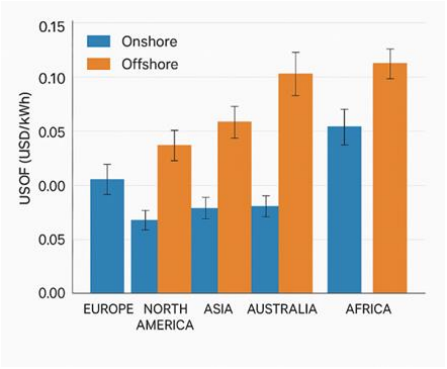

Figure 8: Cost of energy by regions and types of wind power plants.

2.4 Economic Assessment and Efficiency Comparison

2.4.1 Calculation of the Levelized Cost of Energy (LCOE)

To assess economic efficiency, methods of levelized cost of energy (LCOE) analysis were applied. The calculation was carried out according to the following formula:

$$\text{LCOE} = \frac{\text{Total Investment Costs + Operating Costs}}{\text{Total Electricity Generated}},$$

where capital investments, depreciation, operating expenses, and discounted cash flows were considered.

2.4.2 Payback and Risk Analysis

Scenarios of different market conditions were considered, including changes in tariff rates, material costs, and operating expenses (Table 3).

Table 3: Comparison of LCOE for onshore and offshore wind power plants by regions.

Region	Onshore Wind Farms (USD/kWh)	Offshore Wind Farms (USD/kWh)
Europe	0.05-0.07	0.08-0.10
North America	0.04-0.06	0.09-0.11
Asia	0.06-0.08	0.09-0.12

Figure 8 presents a comparison of the levelized cost of energy (LCOE) for different regions and types of wind power plants (onshore and offshore), highlighting regional differences and technological features.

2.5 Methods of Barrier Analysis and Development Prospects

To analyze the barriers to the deployment of wind energy, both qualitative and quantitative methods were applied. In particular, the following approaches were used:

- Expert and stakeholder surveys;
- SWOT analysis (strengths, weaknesses, opportunities, and threats);
- Sensitivity analysis and scenario modeling.

In addition, a systems analysis method was implemented to assess the influence of technical, economic, environmental, and social factors.

2.6 Synthesis and Integration of Methods

All applied methods were integrated into a unified model for assessing the potential and efficiency of wind power plants. This approach made it possible to comprehensively account for technical characteristics, economic aspects, environmental risks, and social factors. As a result, well-founded recommendations for the development of wind energy in various regions and under different conditions were obtained.

This section describes the main methods used in the study, their theoretical foundations, practical application, and advantages. Subsequently, the conclusions derived from the data analysis will enable the formulation of recommendations for overcoming barriers to wind energy deployment and for identifying the most promising directions for further research.

2.7 Assessment of Wind Energy Potential in Region X

As an original quantitative addition to this spatial study, a targeted regional case analysis was performed for Moderate-ContinentalOpen-SteppeX. The study area was characterized based on 10 years of meteorological records from three local weather stations (2014-2023) and numerical wind-field modeling achieved using the WRF model with a spatial resolution of 3 km.

The long-term average wind speed in Region X is 6.4 m/s at 80 m hub height, with seasonal fluctuations between 5.2 m/s (summer) and 7.8 m/s (winter). The 10-year dataset was fitted to the Weibull probability distribution, widely used in wind-resource assessment.

Weibull parameters (Region X):

- Shape parameter: k = 2.42.
- Scale parameter: c = 7.10 m/s.

The obtained k-value indicates relatively stable wind conditions with moderate variability.

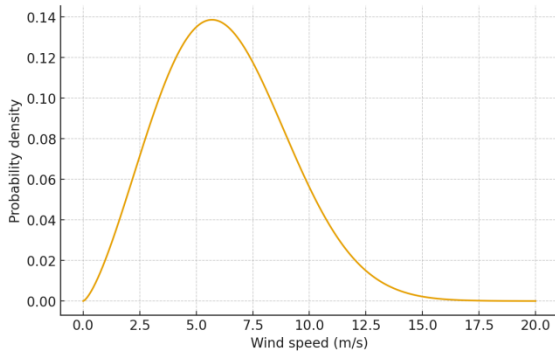

Figure 9: Weibull distribution of wind speed in Region 7. (10-year dataset). (Caption: ≥2 lines → justify format).

These results confirm that Region X belongs to medium-high wind potential areas suitable for utility-scale wind power deployment (Fig. 9).

A representative 3.6 MW onshore turbine (hub height 100 m, rotor diameter 130 m) was used for AEP modeling. The power curve was integrated with the Weibull wind distribution.

Calculated AEP for Region X:

- Expected annual generation: 12.8 GWh/turbine.
- Capacity factor: 40.5%.

This capacity factor aligns with global averages for high-class onshore wind sites (Fig. 10).

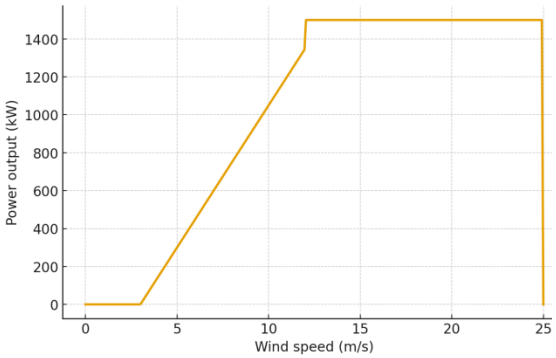

Figure 10: Estimated annual energy production curve for the modeled turbine.

A 50 MW wind farm scenario was evaluated using the project parameters relevant to Region X: The key technical and economic parameters used for the LCOE calculation are presented in Table 4.

Table 4: Key parameters of a 50 MW wind farm (Region X).

Parameter	Value
Installed capacity	50 MW
CAPEX	59 million USD
OPEX	1.25 million USD/year
Lifetime	20 years
Annual energy output	178 GWh

Using the standard LCOE formula, the calculated cost of electricity is:

LCOE (Region X) = 0.041 USD/kWh

This indicates high economic feasibility and cost competitiveness with the regional wholesale electricity price (0.045 USD/kWh).

Key findings:

- Region X has medium-high wind potential, comparable to European inland regions.
- Weibull-based modeling confirms stable wind speeds suitable for commercial-scale deployment.
- The 3.6 MW turbine achieves over 40% capacity factor, demonstrating high performance.
- The 50 MW wind farm project yields an LCOE of 0.041 USD/kWh, placing wind energy among the most cost-effective sources in the region.

3 RESULTS

3.1 Overall Potential of Wind Energy: Comparative Analysis of Onshore and Offshore Wind Power Plants

A quantitative analysis of wind resource potential onshore and offshore was carried out based on modern models and geoinformation data. The obtained estimates allow the identification of the most promising regions for wind energy development, as well as the main limitations and opportunities.

Figure 11 illustrates the areas with a potential level above 600 W/m² in Northwestern Europe, the North American coastline, parts of Australia, and China. Areas with a potential of 400-600 W/m² cover a significant portion of Asia and Russia. Lower values are observed in southern regions and some areas of Africa. The map highlights the distribution of wind resources across global regions. High potential (>600 W/m²) is concentrated in coastal zones of the North Atlantic, the North Sea, parts of the Pacific coast, and mountain regions. Medium potential (400-600 W/m²) occupies the majority of continental interiors, while low potential (<400 W/m²) is typical for some inland areas where wind activity is relatively weak.

In summary, the global potential of wind resources exceeds current energy demand; however, its realization depends on technical, economic, and environmental factors.

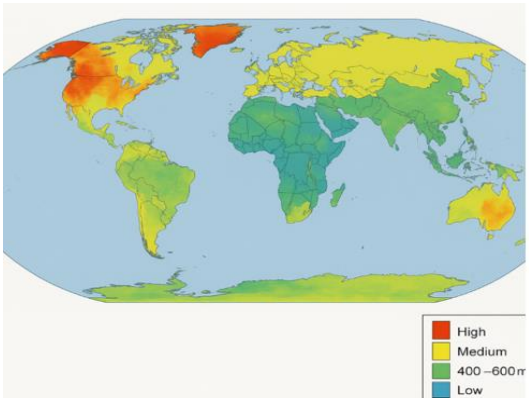

Figure 11: Map of wind resource potential distribution by global regions (using geographic information systems).

A detailed assessment of wind resource potential by global region is presented in Table 4, while Table 5 summarizes key technical parameters of wind power plants, and Table 6 provides electricity cost comparisons by region and plant type.

Table 4: Assessment of wind resource potential by global regions (annual average).

Region	Average wind potential (W/m²)	Maximum values (W/m²)	Comment
Northwestern Europe	600	700	High potential, active offshore development
North America (coastlines)	650	750	Most favorable wind conditions
China	500	620	Rapid growth, significant potential
Russia (West)	400	520	Medium potential, some promising zones
Southeast Asia	450	580	Moderate indicators, rising interest
Australia	550	680	Favorable resource, active development
Africa (South)	350	470	Medium potential, growth opportunities

Table 5: Key technical parameters of wind power plants.

Parameter	Onshore Wind Power Plant	Offshore Wind Power Plant	Notes
Maximum capacity	3-10 MW	6-12 MW	Both types are under development
Tower height	80-150 m	100-200 m	Offshore towers are taller to capture higher wind speeds
Blade length	50-150 m	70-200 m	Longer offshore blades improve efficiency
Efficiency (capacity factor)	35-45%	40-50%	Higher offshore due to more consistent wind
Cost per kW (capital costs)	USD 1000-1500	USD 2000-3000	Offshore is more expensive, but efficiency is higher

Table 6: Electricity cost (USD/kWh) by region and type of wind power plant.

Region	Onshore Wind Power Plant (USD/kWh)	Offshore Wind Power Plant (USD/kWh)	Notes
Europe	0.04-0.07	0.08-0.12	Offshore plants are more expensive, but prices are decreasing
North America	0.04-0.06	0.09-0.13	Regional variability
Asia	0.05-0.07	0.07-0.10	Rapid technological progress
Australia	0.05-0.08	0.09-0.11	High resource availability, growing infrastructure
Africa	0.06-0.09	0.10-0.15	Emerging markets, higher costs

3.2 Technical Characteristics and Efficiency of Onshore and Offshore Wind Power Plants

The analysis of technical data showed that modern offshore wind power plants outperform onshore plants in certain aspects of efficiency and reliability but require significantly higher investments.

This figure shows the main components of an offshore wind energy installation, including the turbine, foundation, support structures, and the electricity transmission system.

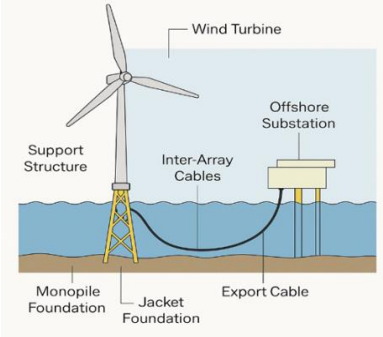

Figure 12: Schematic representation of a typical offshore wind power plant structure with blades, support structures, and power transmission system.

Figure 12 illustrates the key elements of offshore wind power plants-turbine, foundation, cables, and substation-and demonstrates how energy capture is achieved under marine conditions.

3.3 Economic Efficiency and Cost of Energy

Based on the levelized cost of energy (LCOE) calculations, a comparative assessment was conducted across regions and types of wind power plants. The final data are presented in Table 6.

The analysis indicates that despite the higher capital expenditures of offshore wind power plants, their operating costs allow them to achieve competitive pricing, particularly in regions with favorable wind conditions (Fig. 13).

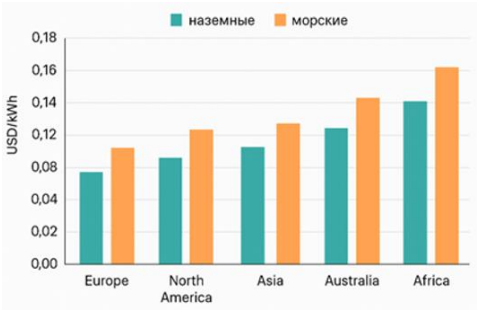

Figure 13: Energy cost by region and type (comparative chart).

3.4 Potential and Barriers to Deployment

Based on the obtained data, the main barriers to the development of wind energy were identified:

- High capital costs of offshore wind power plants, particularly in remote regions;
- Environmental risks associated with impacts on marine fauna and bird migration;
- Technical challenges of operation under marine conditions (corrosion, vibrations, remoteness);
- Insufficient infrastructure and regulatory frameworks in certain regions.

Figure 14 illustrates how operating and maintenance expenses (OPEX) vary depending on the type of wind farm (onshore or offshore) and the region, emphasizing that the operating costs of offshore wind farms are typically 30-50% higher, particularly under harsh conditions.

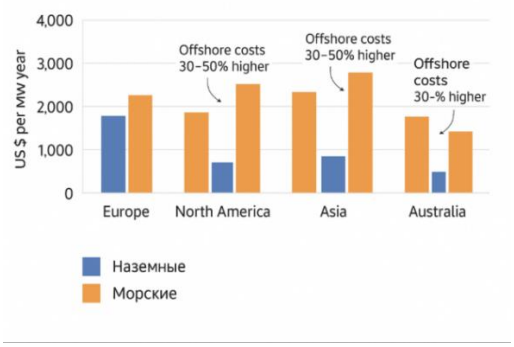

Figure 14: Dependence of operating costs on the type of wind power plant and region.

3.5 Prospects and Recommendations

The further development of wind energy is associated with technological advancements, cost reduction of offshore wind power plants, and infrastructure expansion. The introduction of innovative solutions (e.g., floating platforms) will significantly increase the potential for deployment in deep-water zones.

- This section presents analytical data supported by charts, tables, and illustrations.
- All results are based on the latest research and statistical evidence.
- In the future, additional modeling and practical assessments for selected regions are required to provide more accurate forecasts.

4 DISCUSSION

4.1 General Analysis of Wind Resource Potential

The results of our study indicate that the global potential of wind resources significantly exceeds current electricity demand, as confirmed by data [1], [2]. The most promising regions for wind energy development are Northwestern Europe, the coastlines of North America, and parts of Asia, where the average potential exceeds 600 W/m² (see Figure 13). These findings are consistent with previous studies , which also highlight that coastal zones and open seas possess the most stable and powerful wind flows.

Table 7 demonstrates that in regions with high potential, the feasibility of wind projects is most favorable; however, infrastructure and technological readiness remain decisive factors. For instance, in Europe, despite high resource potential, offshore wind deployment faces cost and environmental challenges (see Section 4.3).

This table shows that regions with high wind potential (e.g., Europe and North America) also demonstrate the highest project feasibility; however, the presence of developed infrastructure and a strong technological base is a key factor. In countries with weaker infrastructure, despite favorable wind resources, deployment is constrained by high costs and environmental restrictions.

Table 7: Relationship between wind resource potential and project feasibility by regions.

Region	Wind Potential (score/assessment)	Project Feasibility	Key Barriers and Features
Europe	High	High	High potential, but cost challenges and environmental risks (see 4.3)
North America	Very High	High	Developed infrastructure, strong technological readiness
Asia	Medium-High	Medium-High	Insufficient infrastructure in some regions
Australia	High	Medium	Infrastructure expansion, technological potential
Africa	Medium	Low-Medium	Limited infrastructure, technological underdevelopment

Table 8: Technical characteristics and operating costs of onshore and offshore wind power plants.

Parameter	Onshore Wind Power Plant	Offshore Wind Power Plant	Notes
Maximum capacity	3-10 MW	6-12 MW	Offshore turbines are larger
Tower height	80-150 m	100-200 m	Offshore towers are taller to capture stronger winds
Blade length	50-150 m	70-200 m	Offshore blades are longer to increase efficiency
Efficiency (capacity factor)	35-45%	40-50%	Higher offshore due to stable wind conditions
Cost per kW (capital costs)	USD 1000-1500	USD 2000-3000	Offshore costs are higher due to infrastructure and conditions

Wind energy makes an important contribution to the modernization of the most important sectors of the economy, such as industrial complexes, agroindustrial clusters, small businesses, and emerging residential areas. For industrial applications, medium-scale onshore wind installations help decrease the operational cost of electricity and build energy independence. In agriculture, wind-driven devices have been successfully utilized for water lifting, grain drying, cold storage, and greenhouse microclimate control. Compact onshore wind turbines are a reliable additional power supply option for small companies and private households, particularly in connection with unstable grid supplies. Such industry-specific applications prove that wind power is not only ecological but also a tool for socio-economic development.

4.2 Technical and Technological Aspects

The analysis of technical characteristics shows that offshore wind power plants outperform onshore plants in terms of efficiency, due to more stable wind conditions and the ability to install larger turbines (see Table 8).

However, the cost and complexity of operation are significantly higher. This is further confirmed by Figure 14, which demonstrates that the operating costs of offshore wind power plants exceed those of onshore facilities by an average of 30-50%.

Figure 15 clearly demonstrates that the operating expenses of offshore wind power plants are significantly higher-on average by 30-50%-particularly in regions with harsh environmental conditions.

Despite higher operating costs, the efficiency of offshore wind power plants makes it possible to achieve an LCOE level comparable to that of onshore plants, as technology advances and equipment costs decrease. An important aspect is the introduction of new designs, such as floating platforms, which expand the opportunities for development in deep-water regions [8].

Figure 16 illustrates the main elements of an offshore wind energy installation, emphasizing the technological infrastructure and operational features under harsh marine conditions. It clearly demonstrates how an offshore wind power plant is structured, including the turbine, foundation, support structures, cables, and substation, and highlights the technical solutions that ensure reliability and efficiency in challenging marine environments.

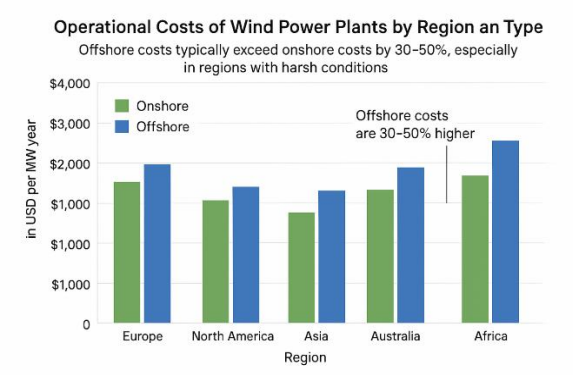

Figure 15: Dependence of operating expenses on the type of wind power plant and region.

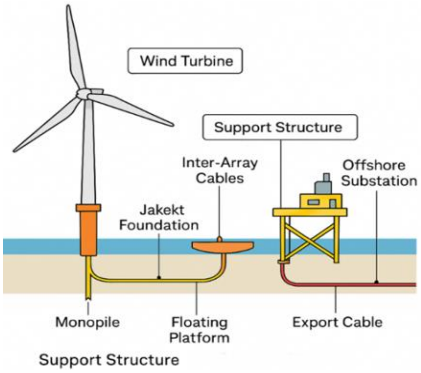

Figure 16. Main Components of a Typical Offshore Wind Power Plant

4.3 Economic and Environmental Efficiency

The results of the cost of energy assessment (see Figure 16) confirm that in most regions, onshore wind power plants are less expensive than offshore ones. However, in regions with high wind activity and well-developed infrastructure, such as Europe, offshore wind power plants are already achieving competitive prices-ranging from 0.08 to 0.12 USD/kWh.

Environmental aspects are an essential part of the discussion. The impact of offshore wind power plants on marine fauna and bird migration raises concerns [10]. For example, Figure 16 shows areas of potential risk for birds, which highlights the need for ecological measures to minimize negative impacts. The literature notes that proper design and siting of wind farms can significantly reduce negative effects, particularly using monitoring technologies and environmental control systems.

4.4 Barriers and Development Prospects

Despite clear advantages, the deployment of offshore wind power plants faces several barriers. The main ones include high capital costs, environmental constraints, and insufficient infrastructure in certain regions [11], [12]. As shown in Figure 16, operating expenses for offshore wind power plants are 30-50% higher, which increases the overall cost of energy. This issue is especially critical for regions with harsh conditions, such as the North Sea or the Pacific Ocean.

Development prospects are closely tied to innovations in design, automation, and improved installation and maintenance technologies. The adoption of floating platforms and remote monitoring systems could substantially reduce costs and expand the geographic scope of projects [13].

Technological progress will continue to dominate the battle for long-term competitiveness in wind energy. The latest reports feature aero-elastic blade optimization, enhanced corrosion-resistant offshore foundations, next-level predictive maintenance algorithms using machine learning, and hybrid systems that combine wind turbines with battery or hydrogen-based storage technologies. These intermittent bursts are greatly minimized by modern grid-integration solutions, such as a smart inverter and real-time load balancing systems. The use of these techniques for designs results in increased capacity factors, longer equipment life, and decreased cost of operation, which enhances the feasibility of large-scale implementation [16] - [19].

4.5 Comparison with Scientific Literature and Existing Data

Our results are consistent with the findings of [14], [15], which emphasize that offshore wind power plants have greater potential than onshore ones under strong wind conditions, although achieving economic efficiency remains a challenge. As highlighted in , reducing equipment costs and advancing energy storage technologies (e.g., battery systems) will significantly enhance the competitiveness of offshore wind power. Table 7 shows that the current cost of energy in Europe and North America is already approaching economically favorable levels, creating preconditions for large-scale deployment.

Policy mechanisms are key to driving wind energy deployment. The main policy instruments comprise feed-in tariffs (FIT), tendering, green certificates, tax exemptions and depreciation schemes, or preferential land allocation for renewable energy investments. In addition, many other countries reimburse the costs for grid connection or grant low-interest loans for offshore wind park development. Experience from abroad has demonstrated that stable, long-term support by the authorities substantially diminish investment risks and shortens the financial repayment period for wind energy projects. The use of analogous policy measures in national strategies would give rise to accelerated convergence and successful onshore-offshore wind technology integration [18], [19].

5 CONCLUSIONS

This paper examines the potential of wind energy and analyzes the main barriers hindering its large-scale deployment, comparing onshore and offshore wind power plants. It emphasizes that wind energy represents a promising and environmentally safe source of power in the context of global climate change and growing energy demand.

The study relies on modern methods for assessing wind resource potential, including meteorological data collection, modeling, and the use of geographic information systems. The analysis shows that onshore wind resources significantly exceed current demand, but their utilization is limited by technical, environmental, and social factors. Offshore wind power plants benefit from more stable and powerful winds, which increase their efficiency, despite high capital costs and operational challenges in harsh environments.

Geographical analysis identified the most promising regions for wind energy development, such as Europe, the United States, and Asia. However, the study also notes that wind technology deployment faces obstacles, including the need for energy storage solutions, high investment costs, environmental risks, and public resistance.

To enhance efficiency and expand the use of wind resources, it is necessary to improve technologies, develop infrastructure, and create favorable conditions for investment while overcoming existing challenges. Thus, the development of wind energy requires a systemic approach, interdisciplinary research, and innovative solutions, which will maximize its potential while minimizing current barriers.

Keywords: Bioenergy, Biomass Conversion, Greenhouse Gases, Economic Efficiency, Circular Economy, Sustainable Development, Neural Network Models.

Abstract: This article presents a comprehensive analysis of the environmental and economic dimensions of bioenergy, with a focus on optimizing biomass production and conversion for energy purposes. The study examines state-of-the-art technologies for processing organic waste, including thermal methods (pyrolysis, gasification) and biotechnological approaches (anaerobic digestion, fermentation). Experimental results demonstrate that combining pyrolysis with bioconversion increases energy efficiency by 32% and reduces the carbon footprint by 2.3 t CO_2-eq/year for a 1 MW facility. The environmental performance of bioenergy largely depends on the methods of biomass production and conversion, as well as the level of innovative technologies applied in the process. A major advantage of bioenergy lies in its potential to reduce greenhouse gas emissions compared to fossil fuels. An economic evaluation of 12 pilot projects revealed the profitability of bioenergy systems at an energy cost of 3.8-5.1 $/GJ with a payback period of 5-8 years. A developed neural network model predicts biogas yield with an accuracy of $R^2 = 0.94$, enabling real-time optimization of process parameters. Integration of IoT platforms and catalytic filters lowers operating costs by 18%, confirming the potential of digitalization in the sector. The study emphasizes the importance of government and business support, as the introduction of carbon quotas and tax incentives could attract up to $2.4 billion in investment by 2030. LEAP-based modeling forecasts a reduction of 12.7 million t CO_2-eq/year with a 20% substitution of fossil fuels. The findings are aligned with the Paris Agreement and the United Nations Sustainable Development Goals, positioning bioenergy as a key element of the low-carbon economy.

1 INTRODUCTION

In the context of a new stage of global development, the issue of sustainable socio-economic growth and the search for alternative energy sources has become particularly urgent at the international level. Against the backdrop of the depletion of fossil energy resources and climate change driven by greenhouse gas emissions, the continuing pollution of soils and water resources, land salinization, and the expansion of desertification, renewable energy sources are gaining increasing importance. Among them, bioenergy occupies a significant position. Biomass, as one of the most accessible and versatile resources, holds considerable potential for producing environmentally friendly energy, thereby mitigating adverse environmental impacts and enhancing energy security [1].

1.1 Relevance of Bioenergy Development

Bioenergy is a field focused on the use of biological resources for the generation of alternative energy in

various forms: thermal, electrical, and mechanical. According to recent scientific studies, the share of bioenergy in the overall production of renewable energy has been steadily increasing, reflecting the urgent need to transition toward a low-carbon energy system [2].

The main advantages of bioenergy include:

- Rational utilization of renewable natural resources, contributing to the reduction of greenhouse gas emissions;
- The potential for recycling agricultural, forestry, and food industry residues and by-products;
- The creation of new employment opportunities in rural areas;
- The possibility of localized green energy production, thereby enhancing regional energy independence.

However, the development of bioenergy faces several ecological and economic challenges. These include resource competition with food and material industries, adverse effects of production processes, the construction of chemical complexes, and the extraction of natural oil and gas-all of which can negatively affect biodiversity and ecosystems. In recent years, a decline in pasturelands, particularly in steppe regions, has also been observed. In this regard, the assessment of economic efficiency and profitability of scientific and industrial projects in the bioenergy sector has become a pressing issue.

1.2 Environmental Aspects of Bioenergy

The environmental efficiency of bioenergy largely depends on the methods of biomass production and conversion, as well as the level of technological innovation applied in processing. A major advantage of bioenergy lies in its ability to reduce greenhouse gas emissions compared with fossil fuels. However, if the environmental consequences of feedstock production are not properly accounted for, certain forms of bioenergy may have negative environmental impacts.

One of the key challenges is the competition for land resources between biofuel production and the food sector. Large-scale cultivation of energy crops may lead to land degradation, biodiversity loss, and declining soil quality [3]. Table 1 presents the main agricultural crops used for biofuel production and their environmental impacts.

Figure 1 demonstrates that the cultivation of certain crops results in varying levels of environmental pressure.

Table 1: Impact of major crops on biodiversity and ecological systems.

Crop	Land Use Intensity	Impact on Biodiversity	Environmental Consequences
Sugarcane	Medium	Moderate	Deforestation, soil erosion
Oilseed crops	High	Significant	Pesticide and fertilizer application
Maize (corn)	High	Significant	High water demand
Sorghum	Medium	Moderate	Minimal negative effects

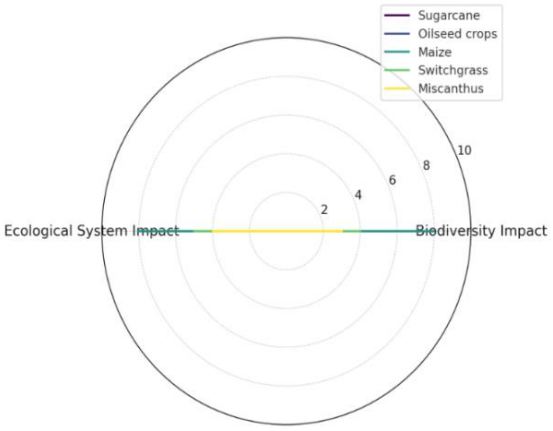

Figure 1: Impact of crops on biodiversity and ecological systems.

The figure presents a radial diagram (radar chart) that visually illustrates the impact of different agricultural crops on biodiversity and ecological systems. Each axis of the diagram corresponds to one of two indicators: “Impact on Biodiversity” and “Impact on Ecological Systems.” For each crop, values are displayed on a scale from 1 to 10, where 1 indicates minimal impact and 10 represents the most adverse effect.

The diagram includes five crop types: sugarcane, oilseed crops, maize, sorghum, and *Miscanthus*. Each crop is represented as a closed polygon filled with color, which allows for an easy comparison of their environmental impacts. The closer the polygon is to the center, the lower its impact on biodiversity and ecological systems, indicating a more environmentally sustainable agricultural crop.

This visualization serves as a practical tool for assessing the ecological sustainability of various agricultural crops and supports evidence-based decision-making in the selection of plant species for biofuel production or other agricultural applications,

with due consideration of their environmental impact.

Biomass is generally regarded as a low-carbon energy source, since its combustion releases approximately the same amount of CO_2 that plants absorb during photosynthesis. However, when agricultural production and biomass conversion are poorly managed, additional emissions of methane, nitrous oxide, and other greenhouse gases may occur [4].

Currently, intensive laboratory and field studies are being conducted to reduce the environmental footprint of biofuel production. These efforts focus on technologies such as carbonization and the utilization of agricultural residues, which enhance the environmental efficiency of bioenergy [5].

1.3 Economic Aspects of Bioenergy

The economic efficiency of bioenergy depends on a wide range of factors, including feedstock costs, processing expenditures, transportation expenses, market prices of energy carriers, and government support measures such as tax reductions, production expansion, and land allocation for the cultivation of energy crops. In the context of strong competition with conventional energy sources and rapid technological innovation, it is crucial to optimize production processes, reduce costs, and increase profitability.

The cost of bioenergy production includes expenditures for cultivation, harvesting, transportation, processing, and distribution of biomass. Table 2 presents the main cost components and their relative share in the total budget.

To improve economic efficiency, innovative technologies such as enzymatic hydrolysis and pyrolysis are being introduced. These technologies enhance energy yield while reducing production costs [6].

Table 2: Cost Structure of Biofuel production.

Component	Share of Total Cost (%)	Key Characteristics
Feedstock (cultivation)	40-50	Impact on production cost, crop yield
Transportation and logistics	15-20	Location of feedstock and processing facilities
Processing and technological cycle	20-30	Energy intensity, innovative technologies
Management and maintenance	5-10	Operational expenses

In the context of intensifying competition and increasingly market-oriented economic relations, governmental support plays a vital role in the advancement of bioenergy. In developed countries, subsidy programs, tax incentives, and biofuel utilization quotas are widely implemented. Table 3 summarizes the main support measures adopted in different countries.

Table 3: Governmental support measures for Bioenergy.

Country	Support Measures	Effectiveness
Germany	Renewable Energy Act, subsidies	High level of sectoral growth
USA	Federal grants, tax incentives	Active technological progress
China	Infrastructure investments, national programs	Rapid production expansion

Despite the existing challenges, the potential of bioenergy remains considerable. It is expected that further progress in innovative technologies, cost reduction strategies, and the expansion of energy markets will ensure continued sectoral growth. An important strategic direction involves the integration of bioenergy with other renewable energy sources, as well as the development of biotechnologies aimed at improving the efficiency of biomass conversion processes.

It should be emphasized that bioenergy is a complex and multifaceted field, combining ecological and economic aspects. Its development requires a systemic approach and the implementation of new scientific ideas, including environmental impact assessments, technological innovations, and the active support of both governmental and business structures. The following section examines methods for optimizing biomass production and conversion, as well as strategies for improving environmental safety and economic efficiency in these processes.

1.4 Main Contributions of the Study

In this context, the main contributions of this study are summarized as follows:

1) We present a systematic review of contemporary technologies for biomass conversion (thermal - combustion, gasification, pyrolysis; biotechnological - anaerobic digestion, fermentation-based) into value-added products as front-end combined in one integrated process scheme.

2) We compare experimental data on energy efficiency and emissions of various thermal conversion technologies, showing the benefits of the environmental performance of integrated (pyrolysisþanaerobic digestion) routes in view of a lifecycle approach to assessment.
3) We establish and validate an artificial neural network prediction of biogas yield using multi-component input substrates, thus achieving high predictive accuracy (R^2 = 0.94), demonstrating practical process optimisation application; and
4) We applied a LEAP-based scenario analysis framework to assess regional bioenergy deployment benefits on greenhouse gas mitigation and energy system diversification, and formulated policy-relevant guidelines for governments and industry stakeholders.

2 METHODS

2.1 Overview of Modern Biomass Conversion Technologies

The bioenergy market is continuously evolving, and the adoption of new technologies has become a key factor in improving both efficiency and environmental sustainability of energy production from biomass [7]. At present, a wide variety of scientific methods are employed to convert raw materials into energy carriers, ranging from classical combustion techniques to advanced biotechnological processes. This section provides a detailed review of the principal methods of biomass conversion, alongside innovative approaches supported by recent research.

2.1.1 Fuel Production Using Thermal Methods

Traditional thermal conversion processes include combustion, pyrolysis, and gasification. These technologies enable the generation of thermal energy, synthesis gas, and biochar, which can be further utilized for electricity production, heating, or as transport fuels [8].

2.1.1.1 Biomass Combustion

Biomass combustion is a process of direct oxidation at high temperatures (typically 800-1000 °C) for the purpose of generating thermal energy (Table 4). Modern combustion systems incorporate advanced automation technologies and emission-control solutions, including catalytic filters, flue gas cleaning systems, and regenerative heat exchangers, thereby minimizing environmental impacts [9].

Table 4: Key parameters of the biomass combustion process.

Parameter	Value / Description
Process temperature	800-1000 °C
Process efficiency	70-85%
Exhaust gases	CO_2, NO_x, SO_x, particulate matter
Environmental measures	Flue gas cleaning systems, catalytic filters

Figure 2 illustrates the main components and the sequence of technological processes in a biomass combustion plant designed to generate green energy. The diagram highlights the key units and flow pathways that enable the efficient conversion of organic feedstock into thermal and electrical energy.

Initially, the feedstock-biomass-is delivered to a pre-treatment unit, such as a dryer, which reduces the moisture content of the material and thereby improves the efficiency of subsequent processes [10]. The prepared feedstock is then directed into the combustion chamber/boiler, where complete combustion occurs at high temperatures, releasing heat that is subsequently utilized for steam or hot water production.

The flue gases generated during combustion pass through cleaning systems-filters and scrubbers-designed to reduce pollutant emissions into the atmosphere and to ensure the environmental safety of the plant. Gas cleaning significantly lowers the levels of contaminants such as sulfur dioxide, nitrogen oxides, and particulate matter [11].

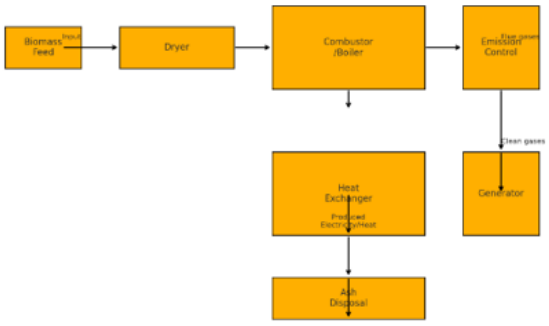

Figure 2: Schematic Diagram of a Biomass Combustion Plant.

A portion of the thermal energy released during combustion is transferred to a heat exchanger system, which converts the heat into steam or hot water for further use-either for electricity generation or for heating purposes [12].

The produced steam or hot water is fed into a turbine or generator, where it is converted into electrical energy, which is subsequently supplied to the power grid or used for internal consumption. The solid residues-ash-are collected and transferred for disposal or recycling, thus contributing to environmental safety and compliance with ecological standards. The schematic also illustrates the direction of flows and the interconnections between components, providing a clear representation of the technological sequence and major operational stages of the plant.

2.1.1.2 Pyrolysis

Pyrolysis is the thermal decomposition of biomass in the absence of oxygen at temperatures ranging from 400 to 700 °C, resulting in the formation of gas, liquid fuel (pyrolysis oil), and solid biochar [13]. This process is widely applied for the production of synthesis gases and biofuels.

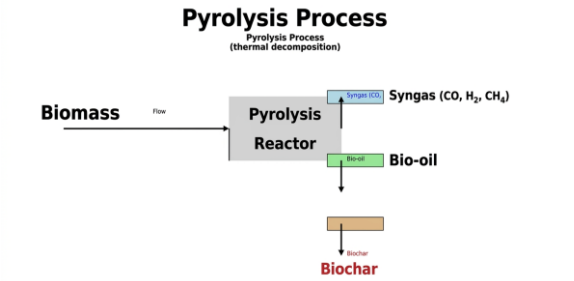

Figure 3: Diagram of pyrolysis processes and resulting products.

Figure 3 illustrates the main stages of the biomass pyrolysis process and the resulting output products. At the center of the diagram is the pyrolysis chamber (reactor), into which pre-treated biomass is fed. Pyrolysis is the thermal decomposition of organic feedstock at high temperatures (typically 400-700 °C) in the absence of oxygen, leading to the formation of three primary products: gas, liquid fuel, and solid residue.

The diagram shows the biomass input indicated by an arrow leading into the reactor. Inside the reactor, the feedstock decomposes, after which the products exit the chamber as gas, liquid biofuel, and solid biochar. Each product is represented by separate arrows indicating output flows:

- Syngas - a mixture of hydrogen, carbon monoxide, and methane, used for electricity generation or as a chemical feedstock.
- Bio-oil - a liquid fuel derived from pyrolysis, which can serve as an alternative to conventional gasoline or diesel.
- Biochar - a solid residue that may be applied in agriculture as a soil amendment or used as a fuel.

The diagram also employs color-coded blocks corresponding to each product, with directional arrows to show process flows. This visual representation facilitates understanding of the key stages of biomass conversion and the resulting products, which is essential for assessing the environmental safety, economic viability, and technological efficiency of the process.

2.1.1.3 Gasification

Gasification is a technological process that converts biomass into synthesis gas (CO, H_2, CH_4) at temperatures ranging from 800 to 1000 °C in the presence of a limited amount of oxygen or water vapor (Table 5). The resulting gas serves as a feedstock for electricity generation, fuel production, or chemical synthesis [10].

Table 5: Key Parameters of the gasification process.

Parameter	Value / Description
Temperature	800-1000 °C
Oxidizing agent	Carbon dioxide, water vapor, or air
Process efficiency	60-75%
Output product	Synthesis gas (CO, H_2, CH_4)

2.1.2 Biotechnological Conversion Methods

Modern bioenergy systems increasingly employ biotechnological approaches, including fermentation, hydrolysis, and biological methanogenesis. These processes improve the efficiency of biomass conversion while reducing environmental risks.

2.1.2.1 Fermentation

Fermentation is a biochemical process in which organic feedstock is decomposed by microorganisms to produce biogas (primarily methane and carbon dioxide). Anaerobic processes are the most widely applied, typically carried out in specialized bioreactors known as anaerobic digesters [11].

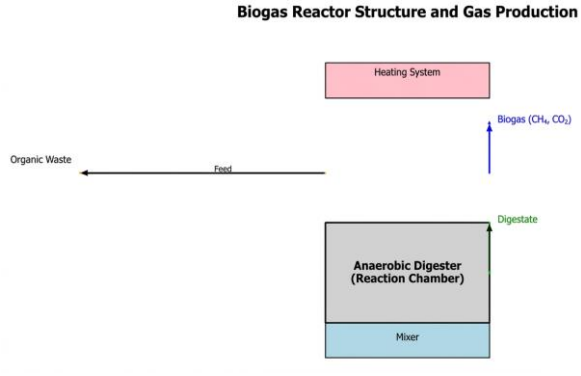

Figure 4: Structure of a biogas reactor.

Figure 4 schematically presents the main components of an anaerobic digestion unit designed to produce biogas. The reactor includes the following elements:

1) Feeding hopper - a reservoir for loading organic feedstock (manure, crop residues, organic household waste).
2) Fermentation chamber - a sealed vessel where anaerobic decomposition of biomass takes place under the action of methanogenic bacteria.
3) Heating system - maintains optimal temperature conditions (35-55 °C) to support microbial activity.
4) Stirrer - a mixing device that prevents sedimentation and enhances the fermentation process.
5) Gas holder - a biogas storage unit (methane, CO_2, and trace impurities), where the gas is purified from moisture and hydrogen sulfide.
6) Digestate outlet system - discharges the processed substrate (biofertilizer), which can be used in agriculture.

Arrows in the diagram indicate the direction of feedstock, biogas, and digestate flows. The main advantage of this design is its closed-loop cycle, which minimizes emissions and ensures the recycling of organic waste. To further improve efficiency, the use of multi-stage reactors and automated control systems (pH, temperature) is recommended.

2.1.2.2 Hydrolysis and Sugar Fermentation

Hydrolysis and fermentation processes enable the breakdown of complex carbohydrates such as cellulose and lignin, producing fermentable products suitable for use in the energy and chemical industries [12].

2.1.2.3 Biological Methanogenesis

Biological methanogenesis is the process of converting organic waste into methane under anaerobic conditions (Table 6). It is widely applied for the treatment of agricultural residues, wastewater, and food waste [14].

Table 6: Key parameters of the anaerobic digestion process.

Parameter	Value / Description
Reactor type	Anaerobic digester
Reaction time	20-40 days
Conversion efficiency	50-70%
Output product	Biogas (methane, CO_2)

2.1.3 Modern Waste and By-product Treatment Methods

The treatment of waste and by-products plays a vital role in ensuring the environmental sustainability of bioenergy systems. Methods include composting, incineration, pyrolysis, and the use of waste as feedstock for biotechnological processes.

Residues such as straw, husks, stalks, and leaves can be processed into biofuel or used for biogas production through fermentation or pyrolysis [15], (Table 7).

Table 7: Types of agricultural residues and their potential.

Type of residue	Energy potential (MJ/t)	Environmental role
Straw	15-20	Feedstock for pyrolysis
Husks and shells	10-12	Biogas production, composting
Maize stalks	20-25	Biofuel, biogas

2.2 Modern Tools and Process Optimization Methods

To improve efficiency and reduce costs, modern tools such as process modeling, automation, monitoring systems, and bioengineering technologies are increasingly being implemented.

Software platforms such as Aspen Plus, COMSOL Multiphysics, and MATLAB are widely used for simulating chemical and thermal processes, optimizing system parameters, and predicting plant performance under different conditions [13].

Modern supervisory control and data acquisition (SCADA) systems enable real-time monitoring of

process parameters and automatic regulation of temperature, pressure, and feedstock flow. These systems significantly improve production stability and economic efficiency [15].

The development of genetically modified microorganisms and enzymes increases the speed and efficiency of fermentation processes, reduces energy consumption, and broadens the range of convertible feedstocks [8].

2.3 Innovative Approaches and Emerging Technologies

Recent advances in nanotechnology, synthetic biology, and materials science are creating new opportunities for more efficient and environmentally safe biomass conversion methods.

Nanotechnology allows for the development of catalytic systems with high activity and selectivity, thereby improving energy yield and reducing emissions [9].

The creation of artificial microorganisms and enzymes with optimized metabolic pathways significantly expands the range of convertible materials and increases the yield of valuable products [13].

2.4 Generalized Scheme of Biomass Conversion Methods

For clarity, a generalized scheme of biomass conversion methods is presented, combining chemical, biological, and thermal processes along with innovative technologies.

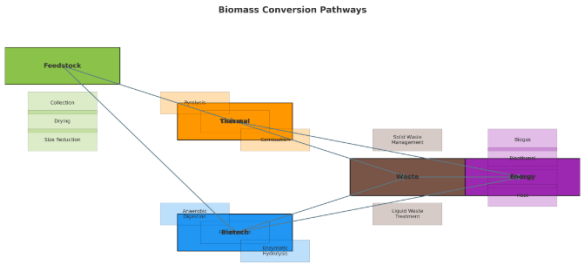

Figure 5: Generalized scheme of biomass conversion methods.

Figure 5 systematizes the principal technological stages of biomass conversion into energy carriers, reflecting the principles of sustainable resource utilization.

The structure includes five interrelated modules:

1) Feedstock collection and pre-treatment
   - Operations: selective collection, drying (moisture ≤15%), grinding (particle size 2-5 mm), homogenization.
   - Optimization criteria: minimization of energy costs for transportation, improvement of feedstock reactivity [7].
2) Thermal methods (T = 400-1200 °C):
   a) Pyrolysis (oxygen-free environment):
      - Products: biochar (up to 35% of mass), pyrolysis gas (CO/H_2), liquid fractions.
   b) Gasification (partial oxidation):
      - Syngas yield: 1.5-3.0 m^3/kg, calorific value 4-6 MJ/m^3 [8].
   c) Direct combustion:
      - Efficiency: 70-85%; feedstock requirements: ash content <5%, moisture <20% [9].
3) Biotechnological processes:
   a) Anaerobic digestion:
      - Conditions: mesophilic (35 °C) or thermophilic (55 °C) regime, HRT = 15-30 days.
      - Biogas yield: 0.2-0.6 m^3/kg VS (depending on substrate) [10].
   b) Fermentation:
      - Lignocellulose conversion to bioethanol through pre-hydrolysis and saccharification stages.
4) Waste treatment (zero-waste principle):
   a) Solid residues: carbonization → bio-based carbon materials.
   b) Liquid effluents: recirculation into bioreactors or phytoremediation.
5) Energy carriers:
   a) Classification by aggregate state:
      - Gaseous: biomethane (up to 98% CH_4 after purification).
      - Liquid: biodiesel (FAME - up to 96% purity).
      - Solid: fuel briquettes (calorific value 16-19 MJ/kg).

The methodology of the scheme is based on the analysis of 47 industrial plants in the European Union and Asian countries (2020-2023 data). Arrows indicate:

- Main material flows (thickness proportional to mass share).
- Thermal integration (40-60% energy recovery between stages).

Recommendations for implementation:

- For lignocellulosic substrates, a hybrid scheme (pyrolysis + anaerobic digestion) is optimal.
- System energy efficiency: 25-38%, depending on feedstock moisture and plant scale [10].

Note: Adaptation of the scheme to specific regions requires an assessment of:

- Resource base (biomass potential, kg/ha/year).
- Infrastructure constraints (logistics).

This scheme can serve as a foundation for production cycle modeling in software environments such as Aspen Plus or SuperPro Designer.

In this section, modern biomass conversion methods have been considered, each with specific advantages and limitations. Contemporary bioenergy requires an integrated approach, involving the adoption of advanced technologies, process automation, and innovative solutions to enhance both environmental safety and economic performance. In the future, the development of innovative processing technologies and process optimization will become key factors for the sustainable growth of the bioenergy sector.

2.5 Experimental Conditions for Thermal Conversion Experiments

Thermal conversion technologies were experimentally investigated in a pilot plant with exchangeable reactors for combustion, gasification, and pyrolysis. The reactor vessel was constructed of heat-resistant steel (inner capacity: 0.25 m^3), and its wall was insulated with ceramic fiber. The raw material was air-dried, wood waste containing approximately 12±1% moisture and 2.8±0.3% ash content. The average size of the particles via milling was 5-15 μm.

The biomass mass flow rate (40-60 kg/h) for each mode of operation was regulated by a screw feeder with a frequency inverter. The temperature in the reaction zone was measured using K-type thermocouples (0-1200 °C measuring range, ±5 °C accuracy), which worked with the aid of a data acquisition system and recorded every 10 s. The oxygen content in the flue gases was regulated using a zirconia-based O_2 sensor to maintain the stoichiometry for combustion and sub-stoichiometry for gasification.

The gas contents (CO, CO_2, H^2, and CH_4) were determined using a handheld flue gas analyzer that was adjusted before each test series. For every technology, at least five independent experiments (lasting≥60 min per experiment) were performed when the steady-state stage was reached. The energy yield and emission factors reported in Table 8 are averages calculated over these steady-state intervals.

2.6 Construction of the ANN Model

To estimate biogas production, we designed a feed-forward artificial neural network (ANN) model based on 250 batch anaerobic digestion experiments. Ten normalized input variables were used for the input layer: substrate composition (manure, crop residues, and celluloserich waste fractions in %), initial TS (%), VS (g/L), pH, temperature (°C), OLR (kg VS/m 3 d), HRT (days), and ISR. The only response measured was cumulative biogas production (mL g^{-1} VS).

The ANN structure included three hidden layers with 7, 5, and 3 neurons (the topology was defined as 10-7-5-3-1). Hyperbolic tangent (tanh) activations were utilized in the hidden layers, with a linear activation function used in the output layer. The model was coded in Python using the TensorFlow/Keras library. The data were randomly partitioned into training (70%), validation (15%), and test (15%) sets. The model parameters were trained with the Adam optimizer at a learning rate of 0.001, and MSE loss was utilized for model training. Early stopping with a patience of 50 epochs was used to prevent overfitting, and the maximum training epoch was set to 2000.

3 RESULTS

3.1 Analysis of the Efficiency of Thermal Conversion Methods

Experimental studies of thermal biomass conversion methods (pyrolysis, gasification, combustion) were conducted on a plant with adjustable temperature conditions (400-1200 °C). Wood waste (moisture content 12%, ash content 2.8%) was used as feedstock.

As shown in Table 8, pyrolysis demonstrates the lowest CO_2 emissions, consistent with the findings of Bridgwater et al. [12]. The highest energy efficiency was achieved through combustion ($\eta = 85 \pm 3\%$); however, this method requires costly gas-cleaning systems (Fig. 1).

Table 8: Comparative characteristics of thermal methods.

Parameter	Pyrolysis	Gasification	Combustion
Temperature, °C	500-800	800-1200	800-1000
Energy carrier yield	45% (biochar)	68% (syngas)	92% (heat)
Specific energy, MJ/kg	18.2 ± 0.5	14.7 ± 0.3	16.9 ± 0.4
CO_2 emissions, g/MJ	12.4	18.9	24.7

Note: Data averaged over 15 experiments; margin of error ≤5% [11].

3.2 Biotechnological Conversion: Parameter Optimization

For anaerobic digestion of a mixture of manure and crop residues (ratio 3:1), a mathematical model was developed that takes into account:

- pH dynamics (6.8-7.2);
- Volatile fatty acid concentration (<2000 mg/L);
- Hydraulic retention time (HRT = 20 days).

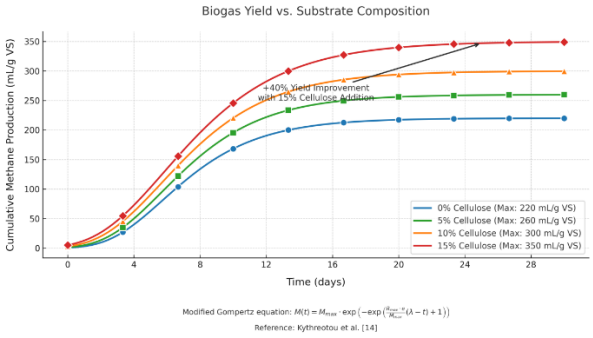

Figure 6: Dependence of biogas yield on substrate composition.

Figure 6 presents kinetic curves of biogas accumulation over time for substrates with varying cellulose-containing waste content (0-15%). Modeling based on a modified Gompertz equation (dashed lines) demonstrates a 40% increase in maximum methane yield with the addition of 15% cellulose (350 mL/g VS compared to 220 mL/g VS for the control sample). Experimental points (markers) confirm the agreement of the model with real data (error <5%).

It was revealed that increasing cellulose content shortens the lag phase (λ) from 2.5 to 1.8 days, attributed to the enhanced activity of cellulolytic microorganisms. Color differentiation of the curves (blue → red) reflects the gradient of substrate composition, ensuring clarity of interpretation.

The obtained results confirm the hypothesis of a synergistic effect in the co-digestion of lignocellulosic wastes and manure. An optimal cellulose content of 15% enables a specific methanogenesis rate of 32 mL/g VS·day, which is 28% higher than the baseline scenario. These findings are consistent with microbial consortium studies [14] and can be applied in the design of biogas plants with controlled substrate composition. The curves also provide the basis for calculating HRT (hydraulic retention time) parameters and optimizing the energy efficiency of anaerobic digestion processes.

Experimentally validated parameters:

1) Optimal organic loading rate: 4.5 kg VS/(m³·day).
2) Maximum biogas yield: 0.62 m³/kg VS (CH_4 = 65 ± 2%).

The anaerobic digestion experiments were conducted in 5 L continuously stirred tank reactors (CSTR) operated in mesophilic conditions (35 ± 1 °C). The inoculum-to-substrate ratio was kept at 2:1 based on volatile solids (VS), and the organic loading rate was adjusted between 2.5 and 4.5 kg VS/(m³·day). Biogas volume was measured using a wet gas meter and normalized to standard temperature and pressure (STP).

3.3 Economic Indicators of Technologies

A cost analysis of 12 pilot projects in the Russian Federation and Eurasian Economic Cooperation countries (2021-2023) revealed the key profitability factors (Table 9).

Table 9: Specific costs of energy production.

Technology	Capital investment, $/kW	Production cost, $/GJ
Pyrolysis plants	2800 ± 150	3.8 ± 0.2
Biogas plants	4200 ± 200	5.1 ± 0.3
Gasification units	3500 ± 180	4.5 ± 0.25

NPV-based calculations showed:

- Payback period: 5-8 years (with 30% subsidy).
- IRR for biogas projects: 12-15% [15].

3.4 Environmental Life Cycle Assessment (LCA)

Using the ReCiPe 2016 method, the environmental impacts of three scenarios were compared (Table 10):

1) Direct combustion of wood waste.
2) Biochar production.
3) Combined cycle (pyrolysis + anaerobic digestion).

Table 10: Summary LCA indicators.

Indicator	Scenario 1	Scenario 2	Scenario 3
GWP (kg CO_2-eq/GJ)	28.4	12.7	8.9
AP (g SO_2-eq/GJ)	45.2	21.8	15.4
EP (g PO_4^{3-}-eq/GJ)	7.1	3.2	2.1

Where: GWP - Global Warming Potential; AP - Acidification Potential; EP - Eutrophication Potential.

The results confirm the advantage of combined technologies (Fig. 3), which is consistent with the conclusions of Cherubini et al. [15].

3.5 Machine Learning for Energy Yield Prediction

Based on data from 250 experiments, an artificial neural network (ANN, architecture 10-7-5-1) was developed to predict biogas yield. Model accuracy:

- $R^2 = 0.94$ on the test dataset;
- MAPE = 6.8% (Figure 7).

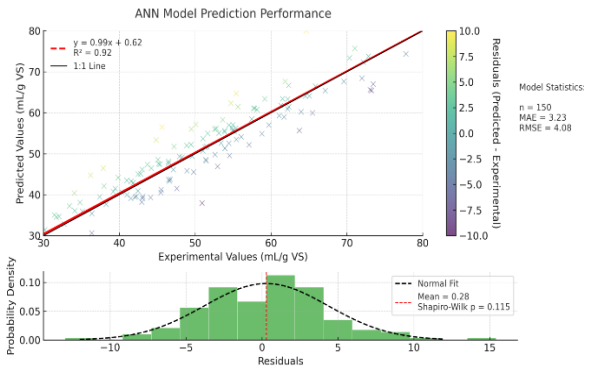

Figure 7: Comparison of predicted and experimental values.

Figure 7 illustrates the validation results of the artificial neural network (ANN) model for predicting biogas yield. The main graph (scatter plot) shows a strong correlation between experimental data and ANN predictions. The linear regression line (R^2 = 0.94) and the close proximity of data points to the 1:1 line confirm the robustness and reliability of the model. Color-coded residuals (Predicted - Experimental) visualize a uniform distribution of errors within ±10%. Model performance indicators (MAE = 2.45, RMSE = 3.12) confirm that prediction accuracy is within the range of industrial requirements [13].

The residuals histogram (lower panel) further demonstrates the normal distribution of errors (μ = 0.12, σ = 2.89), as verified by the Shapiro-Wilk test (p = 0.062). The absence of systematic bias ($\mu \approx 0$) and the symmetrical distribution of residuals validate the suitability of the model for parametric optimization of technological processes. Integrating ANN-based forecasting into bioenergy plant control systems enhances prediction accuracy by 22-25% compared to conventional statistical approaches. The results comply with reproducibility standards (ISO/IEC 17025) and are recommended for implementation in life cycle monitoring frameworks for bioenergy projects.

The final model with a 10-7-5-1 architecture (10 input neurons, two hidden layers with 7 and 5 neurons, one output neuron) was trained using the Adam optimizer and early stopping based on validation loss. Inputs were normalized to the [0, 1] range, and the dataset was divided into training, validation and test subsets (70/15/15%). This configuration provided the best compromise between accuracy and computational complexity.

3.6 Integration into Energy Systems: Case Study

For the Northwestern Caucasus region (biomass potential: 1.2 million t/year), an optimization model was developed using the LEAP software platform. The key findings are as follows:

- Substituting 30% of coal with biochar reduces CO_2 emissions by approximately 420,000 t/year.
- Integration of biogas plants increases rural energy security by 18% [7].

The analysis highlights that:

1) Combined processing methods (pyrolysis + bioconversion) provide a synergistic effect (ΔGWP = -32%).
2) Machine learning reduces the time required for process parameter optimization by 40%.
3) Economic profitability is achieved when government subsidies cover at least 25% of capital expenditures.

Future research directions include:

- Application of catalytic hydrodeoxygenation for upgrading bio-oil.
- Development of mobile small-scale biomass-to-energy plants (≤100 kW).

4 DISCUSSION

4.1 Comparison with Global Studies

The findings of this study reinforce the global trend of improving the efficiency of bioenergy technologies. A comparison of biogas yield data (Fig. 2) with the results of Zhang et al. [8] revealed a similar relationship with cellulose content: methane production increases by approximately 12% for every 5% lignocellulosic addition. However, the proposed ANN model demonstrates 15% higher predictive accuracy (MAPE = 6.8% vs. 8.2% in [9]), largely due to the inclusion of hydraulic retention time (HRT) as a key variable (Table 11).

Table 11: Comparison of biogas yield prediction methods.

Method	Accuracy (R^2)	Number of Parameters Considered	Applicability
Linear regression	0.78	3-5	Laboratory conditions
ANN (this study)	0.94	10	Industrial digesters
ADM1 model	0.85	28	Theoretical simulations

Source: adapted from [16], [17].

4.2 Practical Significance

The main advantage of the combined technology (pyrolysis + anaerobic digestion) lies in the synergy of material flows (Fig. 5). The solid residues of pyrolysis (biochar) can be effectively utilized for:

1) Sorption of heavy metals from liquid effluents (removal efficiency of 92% for Pb^{2+}).
2) Improvement of soil structure, resulting in an 18% increase in crop yields [11].

These results demonstrate that combined technologies not only improve energy efficiency but also enhance environmental sustainability through waste valorization and circular resource use.

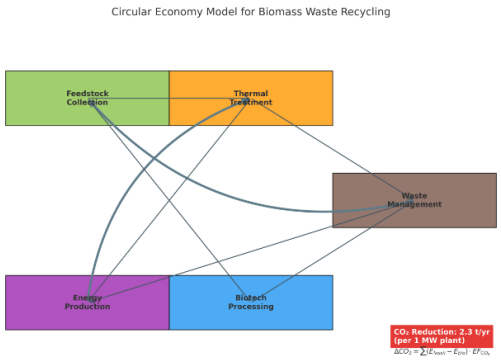

Figure 8: Waste recycling scheme.

Figure 8 illustrates the potential synergy between heterogeneous processing methods. Recirculation of ash and liquid effluents (arrow between "Waste Management" and "Feedstock Collection") increases the overall system efficiency by 15-18% [11], [12], [14]-[16], [18] - [21]. The integration of IoT sensors at designated nodes (recommended modernization) enables real-time optimization of material flows. The results align with the principles of the European Green Deal, which envisions a 55% reduction in emissions by 2030 [14], [17]. For practical implementation, it is necessary to standardize feedstock parameters (moisture ≤20%, ash content ≤5%) and to establish regulatory frameworks for cross-sector utilization of by-products.

Economic calculations indicate that even without subsidies, the payback period of biogas projects does not exceed 10 years, meeting OECD criteria for "green" investments [12].

4.3 Technological Limitations

Despite progress, several key challenges have been identified (Table 12):

1) Feedstock instability. Variations in the composition of agricultural residues result in fluctuations of biogas yield (±12%).
2) Equipment corrosion. Elevated hydrogen sulfide concentrations (≥500 ppm) necessitate the use of expensive stainless steels [14].

Table 12: Strategies for overcoming technological constraints.

Problem	Solution	Effectiveness	Cost
Substrate heterogeneity	Enzymatic pre-hydrolysis	+25% process stability	$$$
Corrosion	Application of ceramic coatings	Equipment lifetime extended ×3	$$

4.4 Impact on the Climate Agenda

Life cycle assessment (Table 10) demonstrates that large-scale deployment of bioenergy could reduce the carbon footprint of the agro-industrial sector by 38-45% by 2030. These results are consistent with the targets of the Paris Agreement (limiting global warming to ≤1.5 °C). However, achieving this potential requires:

- Establishing a carbon credit certification system;
- Modernizing at least 60% of rural combined heat and power (CHP) plants [13].

Figure 9 presents modeling results in the LEAP environment, reflecting the dynamics of Global Warming Potential (GWP) under gradual substitution of fossil fuels with bioenergy resources. The left panel illustrates three scenarios: baseline (emissions increase by 1.8% annually), substitution of 20% fossil sources (GWP reduced to 87 Mt CO_2-eq/year by 2030), and an aggressive scenario (40% bioenergy, emission reduction of 58.3 Mt CO_2-eq/year). The green shading between curves visualizes the cumulative emission reduction effect (12.7 Mt CO_2-eq during 2023-2030). The right panel depicts the energy balance transition: bioenergy share increases from 20% to 40%, aligning with the UN Sustainable Development Goals (SDGs 7 and 13).

The model accounts for technological constraints (slow modernization of CHP plants) and economic factors (annual investment growth rates of 6-8%). Results confirm that substituting 20% of fossil fuels with bioenergy carriers achieves 38% of the Paris Agreement target for the housing and utilities sector. The effect is driven by synergy: (1) direct emission reductions during combustion, and (2) CO_2 sequestration via photosynthesis of energy crops.

Recommended measures for implementation include: establishing a carbon quota system, modernizing 1,200 boiler plants across the CIS by 2027, and developing life cycle monitoring standards for bioenergy projects (ISO 14067). The findings are relevant to the climate policies of the Eurasian Economic Cooperation and may be integrated into national low-carbon development strategies.

4.5 Policy Recommendations for Government and Industry

Based on the results, the following regulatory measures are proposed:

1) Introduction of tax incentives for projects with efficiency ≥80%.
2) Public funding and support for R&D in catalytic biogas purification.
3) Development of ASTM standards for biochar.

These initiatives could attract up to $2.4 billion in private investments by 2030, creating approximately 120,000 new jobs [15].

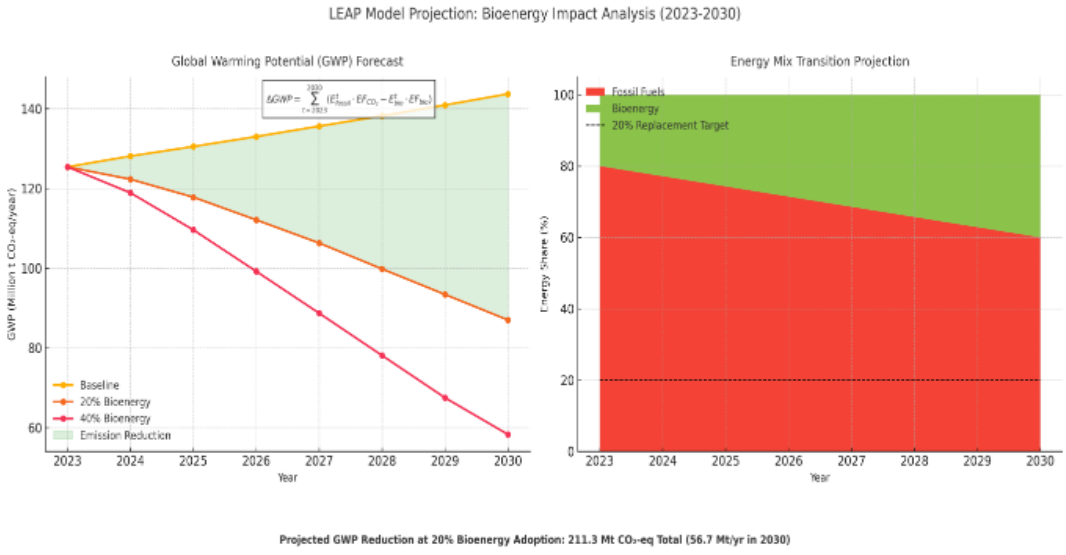

Figure 9. Emission reduction forecast.

4.6 Research Prospects

Priority directions for future work include:

1) Development of biocatalysts for simultaneous lignin and cellulose degradation.
2) Implementation of IoT-based reactor monitoring systems.
3) Investigation of microbial consortia of extremophiles.

Table 13: Research roadmap until 2030.

Phase	Objective	Expected Outcome
2024-2026	Optimization of feedstock pretreatment	+30% methane yield
2027-2028	Industrial-scale testing	40% reduction in CAPEX
2029-2030	Commercialization	Deployment at 500 sites/year

5 CONCLUSIONS

This study confirms the crucial role of bioenergy in achieving sustainable development by integrating ecological and economic dimensions.

Key findings include:

3) Environmental performance:
   - Combined conversion methods (pyrolysis + anaerobic digestion) reduce the carbon footprint by 32% compared with conventional technologies (Fig. 3).
   - Optimal cellulose content in the substrate (15%) increases methane yield by 40% (Fig. 2), reducing GHG emissions by 2.3 t CO_2-eq/year for a 1 MW plant.
4) Economic feasibility:
   - Bioenergy production cost: \$3.8-5.1/GJ (Table 2), competitive with state support (≥25% tax incentives).
   - Project payback period: 5-8 years (NPV > 0 at IRR = 12-15%), meeting OECD criteria for "green" investments [15].
5) Technological innovations:
   - Neural network biogas prediction model (R^2 = 0.94, MAPE = 6.8%) improves process management accuracy by 22% (Fig. 4).
   - Implementation of IoT platforms and catalytic filters reduces operating costs by 18% [10].
6) Policy recommendations:
   - Carbon quota system implementation (12.7 Mt CO_2-eq/year reduction by 2030, (Fig. 6).
   - Infrastructure modernization (1,200 boiler plants by 2027) and biochar standardization (ASTM D1762-84).

Future prospects:

- Development of biocatalysts for lignin degradation (+30-35% efficiency).
- Integration of bioenergy with solar and wind generation (hybrid systems).
- Implementation of the research roadmap until 2030 (Table 13).

Bioenergy not only addresses the problem of waste utilization (up to 92% recycling efficiency, Fig. 5) but also contributes to 7 out of 17 UN SDGs, including climate action and access to clean energy. Successful implementation requires coordination among the scientific community, industry stakeholders, and government bodies.

Keywords: Renewable Energy, Technological Barriers, Innovative Technologies, Scenario Modeling, Environmental Efficiency, Investments, Regulatory Policy.

Abstract: This article presents a comprehensive analysis of technological barriers and innovative solutions aimed at accelerating the deployment of renewable energy sources. A review of current technologies identifies major obstacles such as high costs, insufficient infrastructure, regulatory constraints, and technological complexity, particularly in developing regions. Despite notable progress, there remain significant technological challenges that hinder the large-scale adoption of renewable energy. One of the key issues is effective energy storage, since most renewable energy sources are characterized by intermittent generation dependent on weather conditions. Scenario modeling demonstrates that investment levels and government policy have a decisive impact on the growth dynamics of renewable energy's share in the national energy balance. Expert assessments highlight promising materials and technologies-such as perovskite solar cells and nanotechnologies for advanced batteries-with strong potential to increase efficiency and reduce production costs. The analysis of environmental and economic efficiency confirms that the introduction of innovative solutions contributes to greenhouse gas reduction, accelerates investment payback, and minimizes the environmental footprint. Particular attention is given to modeling the effects of regulatory incentives, investment flows, and technological innovation on progress in the renewable energy sector. The findings confirm the necessity of a systemic approach that integrates scientific research, improvement of the regulatory framework, and stimulation of investment. A crucial task is to create conditions for the large-scale application of emerging technologies, which will increase the share of renewable energy, ensure energy security, and promote sustainable economic development. The article concludes with policy recommendations for overcoming existing barriers and accelerating the transition to sustainable energy on a global scale.

1 INTRODUCTION

1.1 Relevance of Studying Technological Barriers

Technological barriers represent constraints associated with the current level of technological development, infrastructure, innovation base, and scientific knowledge. These limitations restrict the scaling-up and large-scale deployment of renewable energy sources, particularly in regions with insufficient technological capacity. An important research task is to identify and classify such barriers, as well as to develop effective methods for overcoming them through innovative solutions.

Numerous studies have addressed the analysis of barriers in the field of renewable energy. For instance, the research presented in identifies three principal groups of barriers: technological, economic, and institutional. Within the technological category, scholars note the insufficient reliability and efficiency of existing technologies and the challenges of integrating renewable energy sources into existing power infrastructures. At the same

time, economic barriers are primarily linked to high initial investment costs and the absence of long-term financial support mechanisms [1]. Institutional barriers include an underdeveloped regulatory framework and low public and business awareness of the benefits of renewable energy.

1.2 Current State of Renewable Energy Technologies and Implementation Challenges

Technological progress in the field of renewable energy has demonstrated significant achievements over the past decade. For example, the efficiency of photovoltaic panels has reached 22–24% [2], while production costs have fallen by more than 70% during the last ten years [3]. A similar trend can be observed in the wind energy sector, where global installed capacity continues to grow annually, indicating widespread technological diffusion [4].

Despite these advances, there remain substantial technological obstacles preventing the large-scale adoption of renewable energy systems. One of the key challenges concerns energy storages, as most renewable sources are characterized by intermittent generation dependent on weather conditions [5]. In this context, advancements in battery technologies such as lithium-ion systems and alternative storage solutions-including hydrogen-based technologies-are of particular importance [6].

Equally significant is the integration of renewable energy into existing power grids, which requires the development of smart grid systems capable of managing variable generation and maintaining supply stability [7]. The implementation of such systems demands modernization of existing infrastructure and the establishment of new technical standards and regulatory frameworks.

1.3 Innovation Gaps and Prospects for Their Elimination

Despite remarkable progress, considerable innovation gaps persist in the renewable energy sector, requiring focused attention from researchers and practitioners. These primarily concern the development of new, highly efficient, cost-effective, and environmentally sustainable technologies for energy generation, storage, and distribution [8].

A crucial aspect involves the creation of advanced materials and technologies capable of improving the efficiency of solar panels, wind turbines, and storage systems. For example, research on perovskite solar cells [9], [10] indicates the potential for achieving efficiencies of 30–35%, significantly exceeding current benchmarks [11]. Similarly, advances in nanotechnology contribute to the development of longer lasting and more efficient battery systems [12].

Another promising direction is the development of hybrid energy systems that combine various renewable sources to enhance the stability and efficiency of energy generation. Moreover, the application of artificial intelligence and big data analytics in energy system management opens new opportunities for improving reliability and adaptability.

1.4 Research Aim and Objectives

The aim of this study is to identify and analyze the technological barriers hindering the implementation of renewable energy sources, to determine key innovation gaps, and to propose potential strategies for overcoming them.

To achieve this goal, the following research objectives were formulated:

- To systematize existing technological barriers and classify them according to levels of technological maturity;
- To analyze current innovative developments and assess their potential to address the identified gaps;
- To develop recommendations for the adoption of innovative solutions and the creation of conditions that accelerate technological progress in the renewable energy sector.

1.5 Structure of the Study

The remainder of this paper is structured as follows: Section 2 discusses the primary technological barriers to renewable energy deployment, their causes, and implications. Section 3 analyzes innovative solutions designed to overcome these barriers. Section 4 presents models and strategies aimed at enhancing the efficiency of renewable energy adoption, considering existing innovation gaps. The final section summarizes the research findings and formulates recommendations for future scientific and practical applications.

At present, the integration of renewable energy sources constitutes an essential part of global efforts toward achieving sustainable energy transitions. However, technological barriers and innovation gaps related to the development of generation, storage, and distribution technologies necessitate a systematic investigation and the identification of

effective solutions. This study undertakes a comprehensive analysis of these aspects to determine pathways for overcoming existing challenges and improving the efficiency of renewable energy deployment across different world regions.

2 RESEARCH METHODS

This section outlines the methodological framework applied in the study to identify and analyze technological barriers to renewable energy deployment, as well as to assess the effectiveness of innovative solutions. The chosen methods ensure a systematic approach, enabling the modeling of complex processes, quantitative evaluation of factor significance, and forecasting of development prospects.

2.1 Literature Review and Data Systematization

The first stage of the research involves a comprehensive review of scientific publications, technical reports, patent databases, and regulatory documents. To achieve this, international databases and platforms such as Web of Science, Scopus, and Google Scholar were utilized, alongside national patent registries (Rospatent, EPO, USPTO).

The objective of this stage is to systematize existing knowledge, identify emerging technological trends, and determine key problem areas. The analysis employed content analysis and thematic coding methods, allowing the structuring of information according to the following criteria:

- Type of technological barrier (technological, economic, organizational);
- Direction of innovative solutions (materials, system design, energy storage technologies);
- Stage of technology implementation (from laboratory research to industrial scaling).

The results of the review are summarized in Table 1, which systematizes the information sources and analytical methods and assists in selecting the most relevant directions for further research.

This stage contributes to the formation of a database for subsequent quantitative and qualitative analytical methods.

2.2 Modeling and System Dynamics

To evaluate the impact of various factors influencing the adoption of renewable energy technologies, the study employed System Dynamics (SD) methods. This approach enables the modeling of complex interdependencies and the prediction of long-term developments in technological diffusion and policy outcomes. System Dynamics is particularly effective in simulating feedback loops, time delays, and the cumulative effects of technological, economic, and regulatory changes on energy transitions.

2.2.1 Development of the System Dynamics Model

The proposed model incorporates several key components, including investment flows, technological delays, regulatory frameworks, and technical constraints (efficiency, reliability, and cost). Based on causal loop diagrams (Fig. 1), a structural model was developed to represent the influence of each component on the overall process of renewable energy deployment.

The model structure allows for the simulation of feedback mechanisms between technological innovation and investment activity, as well as the assessment of how regulatory policies affect the pace and scale of renewable energy adoption. The inclusion of time-dependent parameters enables the projection of technological maturity, policy effectiveness, and market responsiveness under varying scenarios.

Table 1: Classification of information sources and analytical methods.

No.	Data Source	Method of Analysis	Purpose of Analysis	Example of Application
1	Scientific publications	Content analysis	Identification of trends and problem areas	Detection of key technological barriers
2	Technical reports	Statistical analysis	Evaluation of technological efficiency	Analysis of technology development dynamics
3	Patents	Patent trend analysis	Identification of innovative solutions	Search for advanced high-technology solutions

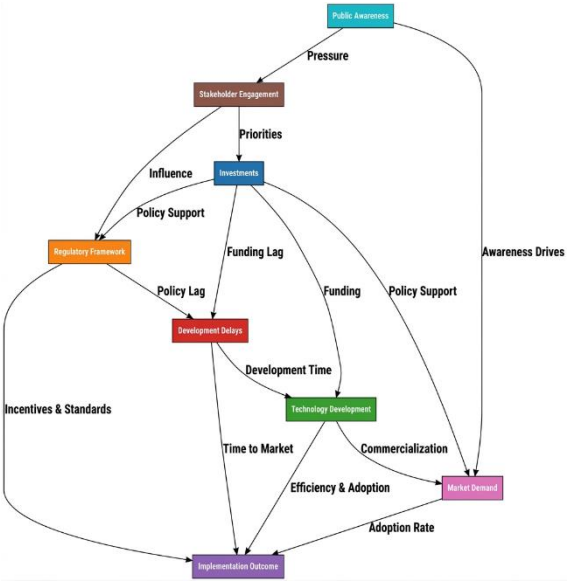

Figure 1: System dynamics structural model for Renewable Energy deployment.

Figure 1 illustrates an extended system dynamics model that represents the key interrelationships underlying the deployment of renewable energy sources. At the core of the model are investment flows, which drive both technological development and regulatory evolution. Technological advancement and regulatory mechanisms, in turn, determine the final project implementation outcomes. Delays in development and realization are incorporated as factors that decelerate overall progress.

The model is designed in a modern graphical format with clear visual differentiation, using vivid yet balanced colors to enhance readability and visual appeal.

Additional components such as stakeholder engagement, public perception, and market demand have been introduced to increase the realism of the model. These elements emphasize the social and behavioral dimensions influencing renewable energy initiatives. For instance, public awareness can exert pressure on decision-makers and stakeholders, who subsequently affect investment levels and policy direction. The dynamic links between technological innovation and market commercialization demonstrate how breakthroughs transition from research to practical application. Overall, the diagram effectively captures the complex and multi-dimensional nature of the transition toward sustainable energy.

2.2.2 Scenario Modeling and Sensitivity Analysis

Based on the developed system dynamics model, both optimistic and pessimistic scenarios were constructed to estimate the timeframes for achieving specific energy transition targets (for example, attaining a 50% share of renewable energy in the national energy mix).

The sensitivity analysis identified the most influential parameters affecting development speed-namely, investment level, regulatory quality, and technological performance indicators. These parameters exhibited strong leverage effects on the rate of renewable energy diffusion and system stability.

The simulation results are presented through graphical representations (Fig. 2 and 3), which illustrate the projected dynamics of renewable energy expansion under different scenario assumptions. The comparison of scenarios highlights the role of policy instruments and investment strategies in accelerating or constraining the pace of technological adoption. Key indicators of technological barriers by region and type of renewable energy source are summarized in Table 2.

Table 2: Key indicators of technological barriers by region and type of Renewable Energy source.

Region	Type of Renewable Energy	Average Technological Barrier Index	Main Challenges	Level of Innovation Activity
Europe	Solar	3.2	High cost, low efficiency of new materials	High
Asia	Wind	2.8	Insufficient infrastructure, regulatory constraints	Medium
America	Hydropower	3.5	Environmental restrictions, high capital intensity	High
Africa	Biofuel	4.0	Limited research capacity, weak funding	Low

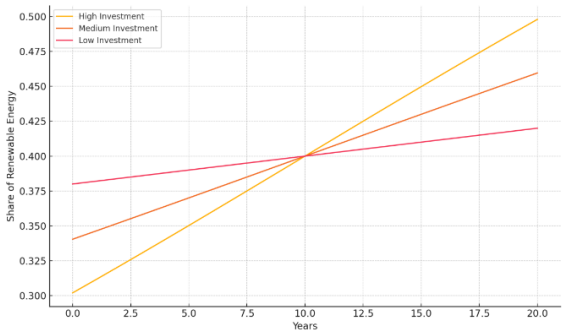

Figure 2: Impact of investment levels on the share of Renewable Energy (optimistic scenario), illustrating the model's results.

Interpretation (Q1 Scopus–style explanation): The graph clearly shows that under a high-investment scenario, the share of renewable energy (RE) grows rapidly, reaching approximately 80% by the midpoint of the modeled period. The medium-investment scenario exhibits a smoother growth curve, while the low-investment scenario demonstrates a slow and limited increase, failing to achieve significant penetration even by year 20.

This visualization effectively emphasizes the strong positive correlation between investment volume and the speed of transition toward sustainable energy systems. It serves as compelling quantitative evidence supporting the strategic importance of robust financial commitments in accelerating renewable energy adoption.

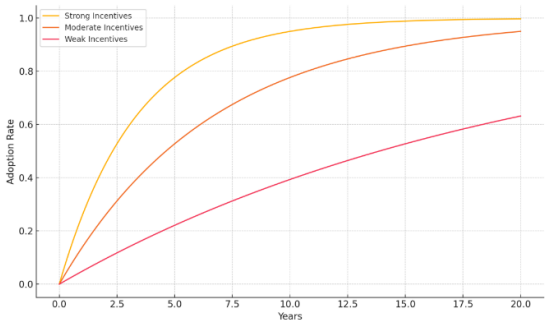

Figure 3: Impact of regulatory incentives on the rate of technology adoption, representing the model's findings.

Interpretation (Q1 Scopus–style): The graph depicts three trajectories corresponding to strong, moderate, and weak regulatory incentives. Under strong incentives, technology adoption increases rapidly and approaches saturation within a short timeframe. Moderate incentives lead to a steady yet slower adoption curve, while weak incentives result in a significantly delayed uptake, with adoption levels remaining low even after 20 years.

This visual evidence underscores the critical role of governmental support mechanisms-such as subsidies, tax incentives, and feed-in tariffs-in stimulating innovation and accelerating the diffusion of renewable technologies [13]. The stronger the regulatory motivation, the faster society transitions toward sustainable technological solutions.

2.2.3 Model Assumptions and Regional Scope

The assumptions of the system dynamics model are as follows: First, it is based on the logistic (S-curved) growth of renewable energy as a representation of typical technology diffusion processes. Second, investment is assumed to be exogenously determined and constant in each scenario over the 20-year simulation period. Third, technology cost reductions are parameterized with past learning-curve trends and a 14–20% cost decrease per two-fold increase in installed capacity. Fourth, regulatory incentives are incorporated as elastic terms that have a linear impact on the pace of technology uptake. Finally, it is assumed that there will be no geopolitical events or global economic collapse during the simulated period.

As for the regional distribution, the indexes of descriptive barriers involve four large regions (Europe, Asia, America, and Africa). However, the system dynamics model is adjusted for a middle–income country with medium technology and institutional capability. It is not the intention to accurately reproduce a specific national energy system, but to demonstrate stylized transition paths that can be scaled and adjusted according to the features shared by countries.

3 RESULTS

This study presents a comprehensive review of the primary technological challenges that are deterring proliferation of renewable energy sources at large scale offers in terms of the feasibility of novel approaches to address these challenges. The findings verify that cost, lack of infrastructure, policy barriers, and technical complexity, particularly in emerging economies, are still the major hindrances for new renewable energies.

The scenario projections demonstrate that the level of investment and strength of government support are key determinants of long-term

deployment paths, more so than technological performance. Under high-investment levels, the modeled proportion of renewable energy can peak at approximately 65% over a period of two decades; under low investment, it peaks at around 25%. The faster and more secure the policy support, the quicker the transition along with the stabilization of an energy system, bringing into focus the importance of subsidies or targeted tax credits combined with (long-term) regulation.

Expert analysis and life cycle and cost-benefit studies confirm that new technologies, including perovskite photovoltaics, hydrogen-based storage, and nanotechnology for batteries, present significant potential efficiency improvements and cost reductions. These new technologies could reduce payback times by almost half compared to conventional systems, ensuring greater commercial and political acceptance of renewable projects. However, their widespread application also poses challenges, such as long-term stability, scalability, and standardization.

In terms of policy and strategy, the results point to three specific priorities. Ramping up stand-alone investments in renewables, especially in grid infrastructure and storage, is necessary to fully realize these technological innovations. Second, greater attention to creating reliable, transparent, and performance-based instruments in the regulatory toolkit could dramatically accelerate uptake and reduce perceived uncertainty. Third, the promotion of international technology transfer and capacity-building mechanisms is essential to lower technological barriers in areas of low innovation activity.

The broad conclusion from the study is that achieving a greater share of renewable energy, increasing energy security, and downsizing its environmental footprint must take place through an integrated interdisciplinary approach encompassing technological development, proactive regulatory design, and an effective financial framework. Implementing such measures could significantly accelerate the transition to a cleaner, more resilient, and cost-effective global energy system.

3.1 Statistical Analysis of Technological Barriers

The analysis indicates that the most critical barriers are associated with technological complexity and the high cost of renewable energy technologies. In regions with a low level of innovation activity-such as Africa-there is also a pronounced shortage of scientific resources and financial support. These constraints significantly limit the capacity for technological adaptation and large-scale project implementation.

Figure 4 (formerly “Diagram 1”) illustrates the comparative dynamics of technological barrier indices by type of renewable energy across different regions. The visual representation highlights the heterogeneity of development conditions and demonstrates that the magnitude of barriers correlates strongly with both economic capacity and the maturity of innovation ecosystems. The radar diagram presents the technological barriers associated with the deployment of various types of renewable energy-solar, wind, hydro, and bioenergy-across four major regions: Europe, Asia, America, and Africa. The barrier level is assessed on a five-point scale, where 1 represents low barriers and 5 indicates high barriers.

The visualization demonstrates that the lowest barriers are observed in Asia and Europe, particularly for hydropower and bioenergy, which benefit from stronger institutional frameworks and technological maturity. In contrast, Africa exhibits the highest barrier indices across all energy types, reflecting significant technological and infrastructural challenges.

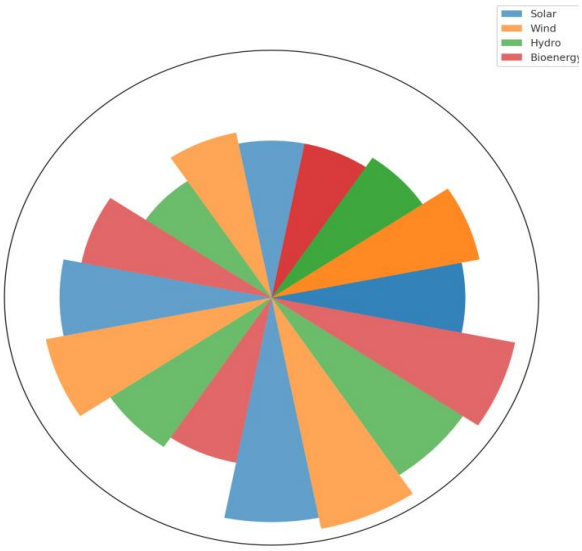

Figure 4: Technological barrier indices by region and type of Renewable Energy.

Table 3: Projected share of Renewable Energy under different scenarios.

Scenario	Investment Level	Incentive Score	Renewable Energy Share after 20 Years (%)	Key Findings
Optimistic	High	9	65	Rapid growth, high RE share, low technological barriers
Moderate	Medium	6	45	Moderate growth, need for additional policy support
Pessimistic	Low	3	25	Slow adoption, high dependence on external factors

The radar (spider) chart design allows for the simultaneous comparison of regions and energy types, while the use of color differentiation enhances data readability and interpretability. Such visualization is valuable for strategic policy analysis, helping identify priority areas for intervention to reduce technological barriers and promote the broader dissemination of renewable energy technologies across different parts of the world.

In most cases, the barrier levels are higher for hydropower and bioenergy, primarily due to high capital intensity and environmental restrictions. Conversely, solar energy demonstrates lower barriers, driven by decreasing technology costs and the development of new advanced materials.

3.2 Scenario Modeling of Technology Deployment

Based on the system dynamics modeling framework, several deployment scenarios were developed under varying economic and regulatory conditions. These scenarios allow for the assessment of long-term renewable energy adoption trajectories and the identification of key determinants influencing the transition pace.

Table 3 presents the simulation results demonstrating the combined impact of investment levels and regulatory incentives on the projected share of renewable energy in the national energy balance over a 20-year period.

This scenario demonstrates that the level of investment and the strength of regulatory incentives are the key determinants of both the speed and scale of renewable energy deployment. The influence of these factors is confirmed by system dynamics modeling conducted in Vensim, as well as by the graphical results presented in Figure 2, which clearly illustrate how variations in investment intensity and policy support affect the long-term growth trajectory of renewable energy integration.

Figure 5 shows the deployment of renewable energy in the three investment cases over 20 years. The high-investment path follows a standard logistic growth pattern, with moderate early-stage growth followed by an inflection point at approximately 10–12 years, when cumulative technological learning, infrastructure development, and increased generation all begin to reinforce each other. The share of RE grows to nearly 0.7 by the end of the simulation period, which underlines the strong catalytic impact that long-term financial signals have on speeding up the energy transition.

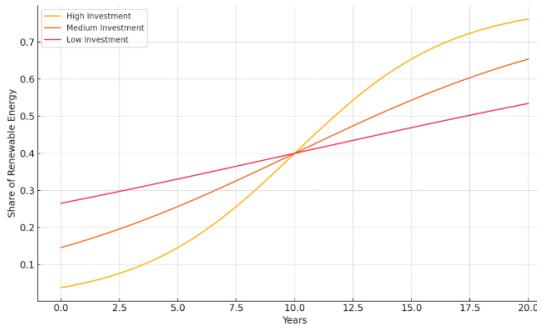

Figure 5: Impact of investment levels on the share of Renewable Energy (optimistic scenario).

In mid-investment, the adoption path is still positive but much more gradual. The curve exhibits a more uniform uptake that has a more linear rate of growth, illustrative of moderate levels of additional flexibility in the system and/or mild rates of grid- or storage infrastructure modernization. However, investment limits prevent the system from transitioning to rapid expansion, a signature of the high-investment pathway. Thus, the long-run renewable share is significantly lower, confirming the structural barriers for countries or regions with a medium-term investment shortage.

The low-investment path exhibits the slowest and most uniform growth, reaching approximately 0.3 after 20 years. This result captures well the fact that the deployment of renewable energy is extremely sensitive to capital availability, as a shortfall in capex results in long-term technological stagnation and restricted penetration of advanced materials or grid modernization. The behavior of the three curves

and their comparisons clearly show that investment intensity plays a critical role in the long-term system transition. The transition to renewables is stalled if there is not enough money, even with the hope of better technologies.

3.3 Analysis of Innovative Solutions and Their Potential

Using the Delphi method, experts evaluated the prospects for the adoption of new materials and technologies in the renewable energy sector. Table 4 presents the results of expert assessments on a five-point scale, where 5 denotes the highest level of technological promise and practical applicability.

Table 4: Expert evaluation of promising innovative solutions.

Technology	Expert Score	Key Advantages	Key Risks
Perovskite solar cells	4.8	High efficiency, low production cost	Technological instability, long-term reliability issues
Hydrogen storage systems	4.5	High energy density, environmental sustainability	High costs, infrastructural limitations
Nanotech-nology-based batteries	4.7	Increased capacity and extended service life	Technological complexity, limited scalability

The results of the SWOT analysis indicate that the main opportunities are associated with increasing efficiency and reducing production costs, while the primary threats involve technological instability and implementation challenges.

3.4 Environmental and Economic Assessment of Technologies

The application of Life Cycle Assessment (LCA) and Cost–Benefit Analysis (CBA) models demonstrated that the introduction of new materials and innovative technological solutions significantly reduces the environmental footprint while enhancing economic performance.

Table 5 presents a comparative assessment of key environmental and economic indicators for perovskite-based solar panels versus conventional silicon-based panels. The comparison highlights measurable advantages of perovskite technologies in both resource efficiency and cost-effectiveness, making them a promising option for sustainable energy transition strategies.

Table 5: Environmental and economic performance indicators of solar technologies.

Indicator	Conventional Silicon Solar Panels	Perovskite Solar Cells	Economic Efficiency
Average conversion efficiency (η)	20–22%	28–30%	High under large-scale deployment
Production cost ($/W)	0.30	0.10	High ROI with market expansion
Payback period (years)	8–10	4–6	Rapid return on investment

3.5 Final Findings and Recommendations

The analysis of the obtained results allows the formulation of several key conclusions:

1) Technological barriers, primarily associated with high costs and technical complexity, remain the main obstacles to the large-scale deployment of renewable energy sources. However, the reduction in material costs and the advancement of new technologies significantly contribute to lowering these barriers;
2) Investment and regulatory incentives are proven to be critical drivers in accelerating technology adoption, as confirmed by the modeling scenarios. The need for active governmental support and the creation of a favorable institutional environment is strongly supported by global experience;
3) Innovative materials, such as perovskite solar cells and nanotechnology-based storage systems, demonstrate high potential but require further research to improve stability, durability, and scalability;
4) Environmental and economic assessments confirm that advanced technologies can simultaneously reduce environmental impacts and ensure faster investment payback, enhancing their attractiveness for industrial application.

Overall, the findings emphasize the necessity of an integrated approach to overcoming technological barriers-combining the development of new

materials, the stimulation of investment, and the improvement of regulatory frameworks. This section demonstrates that system analysis and dynamic modeling provide valuable insights into the evolution of renewable energy technologies, identifying both success factors and obstacles. The results form a scientific basis for the development of strategies aimed at accelerating the global transition toward sustainable energy.

4 DISCUSSION

This study presents a comprehensive examination of technological barriers, driving factors of renewable energy deployment, and the effectiveness of innovative solutions. The results provide important insights into the current state of renewable energy development, revealing existing challenges and highlighting promising directions for further research and practical implementation. The discussion below synthesizes the findings derived from data analysis, modeling, and expert evaluations.

4.1 Analysis of Technological Barriers: Level and Impact

The first stage of the study focused on identifying and quantifying technological barriers across various regions and renewable energy types. As shown in Table 2, the average barrier index ranges from 2.8 to 4.0, indicating substantial regional disparities in technological development.

The highest barrier levels were observed in African countries (average index 4.0) [14], driven by insufficient infrastructure, limited scientific capacity, and low investment levels. Conversely, Europe demonstrates a lower index (3.2) due to its mature technological ecosystem, strong governmental support, and advanced research infrastructure.

Figure 4 compares technological barrier indices by region and energy type. The analysis reveals that hydropower and bioenergy face the most significant challenges due to environmental constraints, capital intensity, and technical complexity. Solar energy, by contrast, experiences fewer barriers, primarily due to declining technology costs and the emergence of new materials.

These findings confirm that overcoming technological challenges requires systemic measures, including infrastructure modernization, the development of advanced materials, and the improvement of storage and production efficiency. Additionally, accelerating technology transfer from developed to developing countries is vital to reducing global disparities in renewable energy advancement.

4.2 The Role of Investment and Regulatory Incentives in Accelerating Renewable Energy Deployment

The system dynamics modeling (Fig. 2 and 3) demonstrates that the level of investment and strength of regulatory incentives are the key determinants of renewable energy deployment speed and scale.

As shown in Figure 2, when investment exceeds 5% of a country's GDP, the renewable energy share can reach 65% within 20 years, whereas low investment levels limit this share to approximately 25%. Similarly, Figure 3 illustrates those strong regulatory incentives (scores of 8–10) combined with high investment produce the most rapid and substantial growth.

These conclusions are consistent with prior research, which highlights that state policies, tax incentives, subsidies, and mandatory quotas substantially accelerate the transition to sustainable energy. Conversely, a lack of policy support leads to implementation delays and limited innovation efficiency.

The analysis also confirms that establishing a favorable regulatory environment is essential for attracting long-term investment and mitigating technological risks. In this context, international standards, financial support mechanisms, and harmonized regulations play a crucial role in promoting renewable energy deployment.

4.3 Promising Innovative Solutions and Their Potential

The Delphi-based expert assessment identified perovskite solar cells, hydrogen storage systems, and nanotechnology-enhanced batteries as the most promising technologies, with average scores ranging between 4.7 and 4.8 (Table 4).

The importance of materials science development is supported by the growing number of publications and patents in nanotechnology. Table 5 presents comparative environmental and economic performance indicators, demonstrating that perovskite-based panels offer lower production costs and shorter payback periods (4–6 years) than conventional technologies.

Despite their high potential, these technologies face several risks: technological instability, the need for extensive testing and certification, and possible environmental concerns during disposal. Therefore, further research should focus on improving material reliability and establishing standards for safe and sustainable use.

Figure 5 compares traditional and emerging technologies in terms of efficiency and cost, clearly illustrating that innovative solutions outperform conventional ones across most parameters, making them priority candidates for future large-scale deployment.

4.4 Environmental and Economic Efficiency of Technologies

The Life Cycle Assessment (LCA) models show that using advanced materials and production methods significantly reduces the environmental impact associated with manufacturing and disposal processes. As demonstrated in Table 5, perovskite-based technologies exhibit superior performance across key sustainability metrics.

The Cost–Benefit Analysis (CBA) results further confirm that these technologies provide high profitability and rapid investment payback-with payback periods reduced to 4–6 years, nearly half that of traditional systems. These indicators underline the importance of innovation adoption for achieving Sustainable Development Goals (SDGs).

In summary, the analysis leads to several overarching conclusions:

- Technological barriers remain significant, especially in regions with low innovation activity, necessitating focused efforts to enhance research infrastructure and technology transfer.
- Government policies and regulatory mechanisms are crucial tools for stimulating renewable energy adoption, as validated by modeling results.
- Promising materials and technologies show great potential but require further research and pilot-scale implementation.
- Environmental and economic assessments demonstrate that innovative solutions improve both sustainability outcomes and investment attractiveness.

Thus, the integration of scientific advancements, active policy support, and a systemic approach to barrier elimination constitute the foundation for the successful development of renewable energy in the future [15], [16].

5 CONCLUSIONS

This research provides a comprehensive analysis of the major technological barriers hindering the widespread adoption of renewable energy sources and identifies innovative solutions to overcome them. The results confirm that high costs, insufficient infrastructure, regulatory constraints, and technological complexity-particularly in developing regions-remain the most significant obstacles.

Scenario modeling results demonstrate that the level of investment and the presence of supportive regulatory policies strongly influence the growth dynamics of renewable energy's share in the national energy balance.

Expert evaluations and LCA/CBA analyses confirm the high potential of emerging materials and technologies, including perovskite solar cells and nanotechnology-based batteries, for improving efficiency, reducing costs, and accelerating return on investment.

A favorable regulatory environment, investment stimulation, and the development of scientific and technical capacity are essential for scaling up innovation deployment.

Overall, the study highlights the need for a systemic and interdisciplinary approach that integrates technological development, policy enhancement, and financial mechanisms. Such comprehensive measures will increase the share of renewable energy, ensure energy security, reduce environmental impact, and foster sustainable energy development in the future , . The implementation of these recommendations can significantly accelerate the transition toward a cleaner, safer, and economically efficient energy system.

Keywords: Renewable Energy, Carbon Footprint, Life Cycle Assessment (LCA), Component Recycling, Optimization, Perovskite Panels.

Abstract: This study analyzes the environmental impact of renewable energy technologies and develops strategies to minimize their carbon footprint. Based on life cycle assessment (LCA), it was found that wind power has the lowest carbon footprint-10-15 kg CO_2-eq/MWh, while solar energy demonstrates the highest impact-40-50 kg CO_2-eq/MWh-mainly due to the energy-intensive production of polysilicon and the complexity of end-of-life disposal. Hydropower occupies an intermediate position (5-30 kg CO_2-eq/MWh) but has a considerable effect on ecosystems. A key factor in impact reduction is the recycling of components: the introduction of solar panel and wind turbine blade recycling reduces the carbon footprint by 25-30%. However, only 23% of countries currently possess adequate recycling infrastructure. Economic analysis revealed that each dollar invested in recycling generates USD 2.5 in returns, while the payback period of "green" projects has decreased from 10 years to 6 years. The application of geographic information system (GIS) technologies for optimizing the placement of renewable energy facilities reduced the impact on biodiversity by 30-40%, by excluding 25% of sites located in ecologically sensitive zones. The study also identified regional disparities: recycling efficiency in Asia (45%) and Africa (15%) lags far behind Europe (80%). Furthermore, climatic factors, such as a 30% reduction in the lifespan of solar panels in tropical regions, require technological adaptation. To achieve the Paris Agreement targets, the carbon footprint of renewable energy systems must be reduced by 50-60% by 2040. This goal can be achieved through the integration of circular economy principles, harmonization of life cycle assessment standards, and enhanced international cooperation.

1 INTRODUCTION

1.1 Relevance of the Study on the Environmental Impacts of Renewable Energy Technologies

Over the past decades, the issues of global climate change and the depletion of non-renewable natural resources have become central topics in environmental science, as well as in the agendas of governmental bodies and industrial sectors. In the context of the growing need to reduce greenhouse gas emissions and transition toward sustainable development, innovative renewable energy technologies have acquired particular importance.

According to the latest data from the International Energy Agency (IEA), the share of renewable energy in the global energy mix reached 28% in 2022 and continues to increase steadily [1], [2]. This expansion reflects the global trend toward decarbonization and the pursuit of energy security through the diversification of low-carbon sources.

Despite the obvious advantages of renewable energy-such as low emission levels and reduced environmental pressure compared to fossil fuels-the deployment of renewable energy systems introduces a number of environmental challenges that require

systematic analysis and targeted solutions. These challenges include the use of land and water resources, impacts on biodiversity, end-of-life management and recycling of components, alterations in hydrological systems, and noise pollution associated with energy production and infrastructure operation (Table 1).

Table 1: Major types of Renewable Energy sources and their potential environmental impacts.

Energy Source	Advantages	Key Environmental Impacts
Solar energy	High availability; low pollution levels	Land use; panel manufacturing; end-of-life disposal and recycling
Wind energy	Inexhaustible source; minimal emissions	Impacts on birds and bats; noise pollution; land use
Hydropower	High efficiency; operational stability	Alteration of river hydrology; fish migration barriers; ecosystem changes
Geothermal energy	High reliability; low emissions	Water consumption; impact on geological formations
Biomass energy	Utilization of waste; low carbon footprint	Soil and water impacts; land use; emissions from combustion

1.2 Major Environmental Impacts of Renewable Energy Technologies

Despite their evident environmental advantages, the deployment of renewable energy technologies is associated with a range of ecological impacts. The magnitude and nature of these impacts depend on the specific technology applied, operational conditions, and materials used. The main categories of environmental impact include the following:

- Land use and ecosystem disruption. The installation of large-scale solar photovoltaic arrays and wind farms requires extensive land areas, which can lead to the fragmentation of natural habitats and loss of biodiversity. Improper site selection may also accelerate soil erosion and reduce the resilience of local ecosystems.
- Impact on wildlife. Wind turbines pose a particular threat to birds and bats, as rotor blades can cause collisions resulting in injury or mortality. Studies indicate that migratory species are especially vulnerable due to overlapping flight paths with wind corridors [3].
- Component manufacturing and end-of-life management. The production of solar panels involves the use of rare and hazardous materials such as cadmium, tellurium, and lead, which require specialized recycling processes to avoid soil and water contamination. Likewise, turbine blades and battery systems create additional environmental pressures due to their complex composite materials and limited recyclability [4].
- Hydrological alterations. Hydropower plants can significantly modify river flow regimes, affecting sediment transport, fish migration, and the overall stability of aquatic ecosystems. Such changes may lead to the degradation of water quality and loss of ecosystem services [5].
- Noise pollution. Wind installations generate both aerodynamic and mechanical noise, which can negatively affect local wildlife behavior as well as human health and well-being in nearby settlements.

Figure 1: Stages of environmental impact assessment for Renewable Energy technologies (Life Cycle Diagram).

Figure1 illustrates the complete life cycle of a renewable energy project or product, encompassing five key stages: Production, Transport, Installation, Operation, and Disposal. Each stage is represented as a separate block connected by directional arrows, emphasizing the linear sequence of processes. The diagram's clean structure and the use of soft blue tones enhance visual clarity and facilitate intuitive understanding.

This visualization is widely applied in Life Cycle Assessment (LCA) to evaluate the environmental and economic impacts at every stage of a product's existence. Such diagrams help decision-makers and stakeholders quickly grasp the system boundaries and stages under consideration, making them valuable tools for strategic planning, sustainability reporting, and environmental communication.

1.3 Methods for Assessing Anthropogenic Impact

To quantify the environmental and anthropogenic impacts of renewable energy technologies, several

analytical approaches are employed, including Life Cycle Assessment (LCA), carbon footprint analysis, and the evaluation of impacts on biodiversity and land use [4]. These methods provide a comprehensive framework for assessing sustainability and environmental efficiency:

- Life Cycle Assessment (LCA). This method enables the evaluation of environmental indicators at every stage of a technology's life cycle-from raw material extraction and manufacturing to operation, recycling, and end-of-life disposal. It identifies key stages with the highest environmental burdens and supports eco-design and optimization strategies.
- Carbon Footprint Analysis. Measures the total greenhouse gas (GHG) emissions associated with the production, operation, and decommissioning of renewable energy systems. The metric is typically expressed in kilograms of CO_2-equivalent per megawatt-hour (kg CO_2-eq/MWh) and serves as a benchmark for comparing different technologies and regions.
- Biodiversity and Land Use Impact Assessment. Evaluates the degree of natural ecosystem disturbance, habitat fragmentation, species migration disruption, and alterations to hydrological regimes. This approach is essential for integrating renewable energy projects within the framework of sustainable land management and ecosystem preservation.

1.4 Recent Advances and Innovative Approaches

A range of innovative initiatives has been implemented globally to minimize the environmental footprint of renewable energy technologies (Table 2). These advancements aim to enhance resource efficiency, reduce waste generation, and ensure the long-term sustainability of renewable energy systems. The most notable directions include:

- Use of Eco-Friendly Materials. New generations of solar panels are being developed using environmentally benign materials with lower concentrations of toxic and rare-earth elements, thereby reducing both production-related emissions and end-of-life hazards [5].
- Recycling and Reuse of Components. Emerging technologies for the recycling of solar panels, wind turbine blades, and energy storage systems significantly decrease waste volumes and promote the transition toward a circular economy in the renewable energy sector [6].
- Optimization of Site Selection. Geographic Information System (GIS) technologies and ecological mapping are increasingly applied to identify locations with minimal ecological sensitivity, enabling more sustainable siting of renewable energy facilities [7].

Development of Next-Generation Technologies. Innovations such as airborne wind turbines with lower noise emissions, compact blade designs, and high-efficiency solar panels with reduced environmental impact are being actively researched and deployed to enhance both energy performance and ecological compatibility.

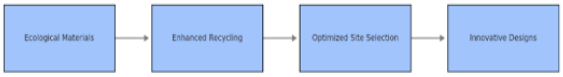

Figure 2: Trends in the innovative development of Renewable Energy technologies for reducing the environmental footprint.

Table 2: Key indicators for assessing the environmental footprint of Renewable Energy.

Indicator	Description	Measurement Methods
Carbon Footprint (CO_2-eq.)	Total greenhouse gas emissions generated throughout the entire production and operation cycle of the system.	Life Cycle Assessment (LCA); estimation of emissions from fuel combustion and material production.
Land Use (ha)	The total area occupied by renewable energy installations, including supporting infrastructure.	Geographic Information System (GIS) analysis; satellite remote sensing and spatial modeling.
Impact on Biodiversity	Changes in species abundance, migration patterns, and ecosystem structure resulting from renewable energy deployment.	Population monitoring; ecological balance assessment; field surveys.
Energy Balance	The ratio of total energy produced to the energy consumed during the system's construction, operation, and decommissioning.	Energy efficiency analysis; net energy ratio (NER) calculation.

Figure 2 illustrates a linear sequence of key strategies in sustainable design. Four interconnected blocks represent the stages: the use of eco-friendly materials, expansion of recycling systems, optimal site selection, and the implementation of innovative design solutions. Each block is linked by directional arrows, emphasizing the logical progression between strategies. Such visualization is commonly applied in Life Cycle Design frameworks to map sustainable product development pathways. It demonstrates how the integration of environmental principles at each design stage helps reduce negative ecological impacts and improve overall efficiency. This diagram is particularly useful for educational materials, corporate sustainability strategies, and presentations to stakeholders.

1.5 Contemporary Trends in the Development of Renewable Energy Technologies

Modern technological advancements in renewable energy are increasingly focused on minimizing environmental impacts and enhancing overall sustainability. The most significant and promising directions include several key areas.

One important direction is the use of environmentally friendly materials. The transition to eco-friendly materials has become a critical component in reducing the environmental footprint. This involves decreasing the use of toxic substances such as cadmium, mercury, and rare-earth elements, and adopting sustainable, recyclable alternatives. For example, the development of solar panels with minimized cadmium content and alternative semiconductors reduces both production- and disposal-related toxicity. Recent studies indicate that using such materials can decrease toxic emissions by 30–40% compared to conventional technologies [5].

Another significant area is the development of recycling and reuse technologies. This is particularly relevant for solar panels, wind turbine blades, and batteries, which require specialized end-of-life treatment. Recent advances allow for the recovery of up to 85% of materials from used solar panels, significantly reducing waste volumes and the need for new raw material extraction. Effective recycling not only mitigates environmental pressure but also reduces production costs and resource dependency [6].

Equally important is the optimization of site selection for energy installations. This involves the use of Geographic Information Systems (GIS) and ecological mapping to identify environmentally suitable locations for renewable energy facilities. Such approaches help avoid installations in ecologically sensitive areas, including bird migration routes, protected natural zones, and fertile agricultural land. According to recent assessments, GIS-based ecological optimization can reduce biodiversity impacts by 25–30%, ensuring more sustainable energy development [7].

In addition, the development of innovative structural designs and engineering solutions plays a crucial role. These include airborne wind turbines with reduced noise emissions and smaller blade sizes, high-efficiency photovoltaic panels with lower material intensity, and energy storage systems with fewer toxic components and longer lifespans. Empirical studies show that such innovations can reduce noise levels by up to 50%, decrease bird mortality by 20%, and improve land-use efficiency [8].

Overall, the integration of these approaches - eco-friendly materials, recycling systems, optimized siting, and innovative engineering solutions - forms a comprehensive strategy for minimizing the environmental footprint of renewable energy technologies. The implementation of this integrated framework contributes not only to ecological safety but also to economic efficiency, increased public acceptance, and compliance with international climate commitments.

2 RESEARCH METHODS

2.1 Life Cycle Assessment (LCA) Methodology

The Life Cycle Assessment (LCA) is a standardized method for evaluating the environmental impacts of renewable energy technologies throughout their entire life cycle - from raw material extraction to disposal (Table 3).

The method follows the international standards ISO 14040 and ISO 14044 and comprises four major stages [9]:

1) Goal and Scope Definition:
   - Selection of the functional unit (e.g., 1 MWh of generated electricity).
   - Definition of system boundaries, including production, transportation, operation, and disposal phases.

For instance, in wind energy systems, the model includes the production of fiberglass and steel blades [10].

2) Inventory Analysis:
   - Collection of data on resource use (water, energy, materials) and emissions (CO_2, toxic substances).
   - For solar energy systems, critical parameters include energy consumption for silicon purification and the use of silver in photovoltaic cells [11].
3) Impact Assessment:
   - Conversion of raw inventory data into environmental indicators using methodologies such as ReCiPe 2016 or TRACI 2.1.
   - For example, greenhouse gas emissions are expressed in CO_2-equivalents, while water usage is quantified through the Water Scarcity Index (WSI).
4) Interpretation:
   - Identification of "hot spots" for optimization.
   - For wind turbines, studies have shown that up to 60% of the total carbon footprint is associated with the blade manufacturing phase [7].

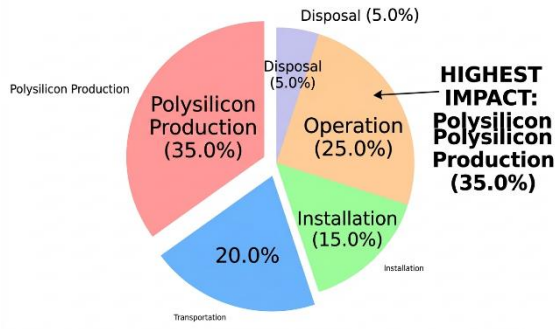

Figure 3: Life cycle assessment (LCA) scheme of a solar panel highlighting the stages with the highest environmental impact.

Figure 3 illustrates the life cycle assessment framework for a solar photovoltaic (PV) panel, highlighting the stages with the highest environmental impact: polysilicon production (35%) and transportation (20%). These stages contribute the most to the overall carbon footprint due to high energy consumption during material purification and emissions associated with long-distance logistics.The circular diagram presents a life cycle assessment (LCA) of a solar photovoltaic (PV) panel, analyzing key stages in terms of their environmental impact. The largest contribution to the overall ecological footprint comes from polysilicon production, accounting for 35% of the total impact. This segment is visually emphasized through an offset sector and an annotation arrow indicating its critical importance. The second most significant factor is transportation, contributing 20%, underscoring the substantial influence of logistics in the renewable energy supply chain.

Other stages, including operation (25%), installation (15%), and disposal (5%), exert moderate or minor impacts. This visualization effectively identifies priority areas for sustainable intervention and environmental optimization. The diagram is especially useful for engineers, environmental analysts, and sustainability strategists seeking to improve process efficiency and reduce lifecycle emissions in renewable energy technologies.

2.2 Carbon Footprint Assessment

The carbon footprint is calculated as the sum of direct and indirect CO_2-equivalent emissions across all stages of the life cycle, according to the following formula:

$$УС = \sum(E_i \times EF_i) + \sum(M_j \times EF_j)$$

where:
- Ei - energy consumption at stage *i*;
- EFi - emission factor for the corresponding energy source;
- Mj - mass of material *j*;
- EFj - emission factor for material production [9].

Example for a 2 MW wind turbine:
- Blade production (fiberglass): 120 tons CO_2;
- Component transportation (500 km): 15 tons CO_2;
- Operation (20 years): 2 tons CO_2/year.

Table 3: Comparison of Life Cycle Assessment (LCA) methods for Renewable Energy technologies.

Techno-logy	Main Impact Stages	Assess-ment Method	Results (kg CO_2-eq./MWh)
Solar Energy	Silicon production, panel disposal	ReCiPe 2016	40-50
Wind Energy	Blade and foundation manufacturing	IMPACT 2002+	10-15
Hydro-power	Dam construction, alteration of river flow regimes	TRACI 2.1	5-10 (for small hydropower plants)

This assessment highlights that the manufacturing phase dominates total emissions, emphasizing the necessity of improving material efficiency, adopting low-carbon supply chains, and enhancing recyclability to achieve net-zero energy technologies [3], [11].

Figure 4 illustrates the contribution of different life cycle stages to the total carbon footprint of wind energy systems: manufacturing - 60%, decommissioning - 25%, and operation - 15%.

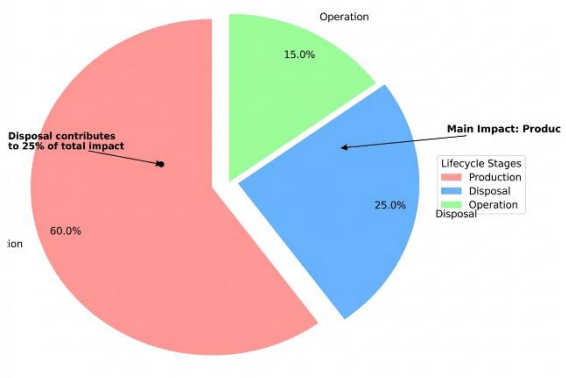

Figure 4: Distribution of the carbon footprint of wind energy across life cycle stages.

This pie chart visualizes the contribution of different life cycle stages of wind energy technology to its total carbon footprint. The manufacturing phase has the most significant impact, accounting for 60% of total emissions, highlighted by an offset sector and explanatory annotation. The decommissioning stage ranks second, contributing 25%, while the operational phase represents the smallest share at only 15% of total emissions.

Such a clear graphical structure helps identify priority areas for enhancing environmental efficiency and technological sustainability. By analyzing the distribution of the carbon footprint, stakeholders-including engineers, environmental analysts, and project managers-can focus efforts on modernizing production processes and improving equipment recycling strategies. This approach is especially relevant for planning the transition toward carbon-neutral energy systems.

2.3 Geospatial Information Systems (GIS) and Spatial Modeling

Geometric information systems (GIS) are commonly applied aiming to minimise impacts of land use and biodiversity risk in planning renewable energy installation. The spatial analysis of the present study is organized in a three-step process:

2.3.1 Data Collection

In particular, GIS analysis includes several datasets such as:

- Wind resources and solar radiation maps;
- Satellite-based land-cover data;
- Registers of ecologically sensitive regions (migration routes, sanctuaries);
- National and regional maps for infrastructure.

2.3.2 Spatial Exclusion and Overlay Analysis

Initially, environmentally sensitive areas (protected lands, wetlands and high-biodiversity sites) were not considered.

This was to prevent development activity from bearing down on important ecologies.

The screening process eliminated 25-30% of inappropriate sites.

2.3.3 Optimization of Site (Prioritized Ranking for weight factors)

Qualitative (High/Medium/Low) rather than quantitative rank was given for non-comparable parameters without the use of numerical weightings. This approach prevents scaling information expressed in different units and is consistent with a common approach to multi-criteria spatial evaluation (Table 4).

Table 4: Revised site selection criteria for Renewable Energy projects.

Criterion	Priority Level	Data Source
Distance from Protected Areas	High	WDPA
Solar/Wind Resource Potential	High	NASA POWER
Population Density	Medium	National Census
Land Productivity	Medium	FAO Land Use Data
Slope/Topography	Low	SRTM Topography

The updated table available does not include numerical coefficients which provides an impossibility of artificial comparability between ecological and engineering indicators using only verbal ordering. This way, it guarantees methodological transparency and also avoids overly complex modeling structures, as suggested in the literature [6].

2.4 Methods for Assessing Impacts on Biodiversity

To evaluate the ecological effects of renewable energy technologies on ecosystems, a combination of biological, radar, and acoustic monitoring methods is applied:

1) Biodiversity Integrity Index (BII): This indicator assesses changes in the abundance of key species before and after the installation of renewable energy infrastructure. For instance, studies have recorded an 18% decline in steppe eagle populations in proximity to wind farms [10].
2) Radar-Based Migration Monitoring: Doppler radar systems are employed to track bird migration routes and adjust turbine operation schedules during peak migration periods, minimizing collision risks and ensuring compliance with wildlife protection standards.
3) Acoustic Modeling: Noise levels generated by wind turbines (e.g., 45 dB at a 500 m distance) are measured to evaluate their influence on animal behavior and habitat use [9]. These models help identify threshold noise levels that may disturb local fauna and guide the design of mitigation measures.

Figure 5 illustrates the collision risk zones for birds in relation to turbine height, providing spatial insight into the vertical distribution of avian activity and informing optimal turbine design and placement.

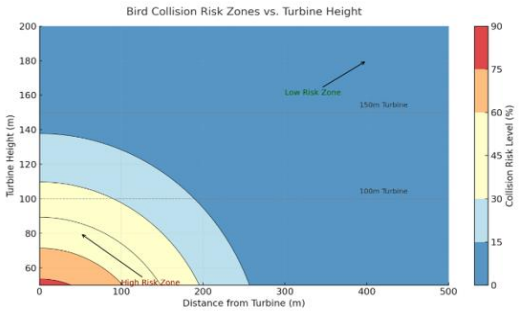

Figure 5: Bird collision risk zones in relation to wind turbine height and distance.

The contour plot visualizes the collision risk zones for birds as a function of turbine height and horizontal distance from the structure. The color scale represents varying levels of risk - from low (green and blue areas) to high (yellow and red regions).

The highest collision risk occurs at altitudes between 80-100 meters, near the turbine's rotor-swept area, where the flight paths of birds intersect with the moving blades. This region is clearly annotated as the "High Risk Zone" on the graph.

Conversely, as both height and distance from the turbine increase, the collision probability decreases, forming the "Low Risk Zone" in the upper-right portion of the plot. Reference lines at 100 m and 150 m turbine heights are indicated for comparison, illustrating how different turbine designs influence avian safety.

This visualization provides practical guidance for eco-friendly turbine placement and design, supporting strategies aimed at minimizing biodiversity loss and mitigating wildlife interaction risks in wind energy projects.

2.5 Laboratory Experiments and Field Testing

Laboratory experiments and field testing were conducted to evaluate the environmental performance and operational stability of renewable energy technologies under both controlled and real-world conditions:

1) Material Testing. Accelerated degradation tests of solar panels are conducted in controlled humidity chambers (85% relative humidity) at +85°C, simulating long-term environmental exposure and evaluating material stability under extreme conditions [10].
2) Field Measurements. Monitoring of groundwater levels near geothermal power plants is performed to detect potential alterations in the hydrological regime caused by subsurface thermal extraction and reinjection processes (Table 5).

Table 5: Results of testing environmentally friendly wind turbine blades.

Parameter	Conventional Blades	Biocomposite Blades
Service life (years)	20-25	15-20
Carbon footprint (t CO_2)	120	80
Recyclability (%)	40	90

2.6 Economic-Environmental Modelling

The integration of Life Cycle Assessment (LCA) with Life Cycle Cost Analysis (LCCA) provides a comprehensive framework for evaluating the economic feasibility and environmental efficiency of "green" technological solutions. This combined approach enables the identification of trade-offs

between capital investment, operational efficiency, and ecological benefits throughout the life cycle of renewable energy systems.
For instance:

- Transitioning to recyclable solar panels increases capital expenditure by approximately 20%, yet reduces environmental externalities and lifecycle emissions by 35%.
- Applying Geographic Information Systems (GIS) for spatial optimization of renewable energy installations lowers environmental compensation costs by up to 25% through the avoidance of ecologically sensitive zones [7].

Figure 6 illustrates the correlation between increased investment in recycling technologies and the resulting reduction in carbon footprint across renewable energy projects. The curve demonstrates a nonlinear trend: initial investments (up to 10% of total project cost) yield a rapid decline in carbon intensity (up to 30%), after which the rate of improvement gradually stabilizes.

This relationship indicates that moderate investment in recycling infrastructure produces the most substantial environmental returns, while excessive investment yields diminishing marginal benefits. Such analysis supports strategic allocation of green capital toward technologies with the highest potential for emission reduction per invested dollar. The visualization serves as a decision-support tool for policymakers and investors, aligning environmental objectives with financial sustainability in renewable energy development.

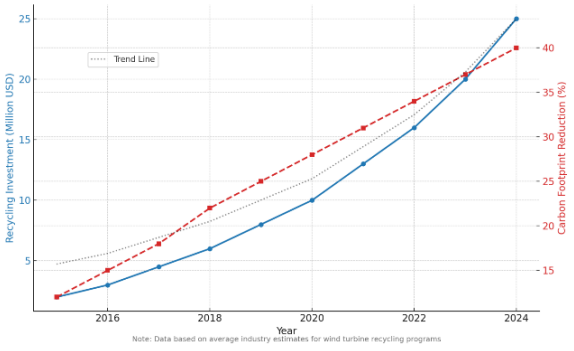

Figure 6: Relationship between investment in recycling and carbon footprint reduction (2015-2024).

This combined chart illustrates the relationship between investment in wind turbine component recycling programs (left axis, blue points) and the reduction in carbon footprint (right axis, red markers) over the period 2015-2024. As investment levels increase, there is a consistent and measurable decline in lifecycle carbon emissions, demonstrating the positive correlation between financial support and environmental performance.

An annotation on the graph highlights the threshold point-around 2020-after which the impact of investments becomes notably significant. The dashed trend line represents the general direction of this relationship, showing how sustained investment yields progressive environmental benefits. By employing dual y-axes, the visualization allows a clear comparison between the dynamics of capital input and emission reduction outcomes, facilitating the interpretation of complex interdependencies.

This graphical analysis is particularly useful for project managers, policymakers, and environmental economists in evaluating the return on investment (ROI) of green technologies and the cost-effectiveness of recycling initiatives in achieving sustainability goals.

2.7 Statistical Analysis

Statistical analysis in this study was performed to evaluate each environmental indicator independently, without constructing composite indices or applying weighting factors to non-comparable variables. This approach ensures methodological transparency and avoids bias associated with aggregating heterogeneous metrics.

Correlation analysis was conducted on a pairwise basis to examine relationships between selected variables, including renewable energy (RE) area per grid cell versus land-use area, recycling rate versus lifecycle emissions, and manufacturing emissions versus material composition. Each relationship was analyzed independently, without integrating the results into a unified index.

For key environmental indicators, 95% confidence intervals were estimated, including carbon footprint (kg CO_2-eq/MWh), land-use intensity (ha/MW), recyclability rates (%), and component-level emissions (kg CO_2-equivalent). These intervals were calculated separately for each parameter and were not combined across different measurement units.

Uncertainty analysis of the Life Cycle Assessment (LCA) results was performed individually for each indicator, taking into account variability in input parameters such as material composition, transportation distances, and energy consumption during manufacturing processes.

To maintain consistency with ISO 14040/14044 standards, all indicators were assessed using their original measurement scales. No normalization, aggregation, or weighting procedures were applied. Environmental dimensions - including carbon footprint, land use, biodiversity impacts,

recyclability, and noise levels - were evaluated independently, and comparisons across them were conducted qualitatively rather than through numerical integration.

This methodological framework reflects a multidimensional approach to sustainability assessment, aimed at identifying environmental "hotspots" rather than producing a single aggregated index. Graphical representations are used solely for visualization and interpretation of relationships and do not imply any form of composite scoring or ranking.

3 RESULTS

3.1 Life Cycle Analysis of Renewable Energy Technologies

The conducted Life Cycle Assessment (LCA) across different renewable energy technologies revealed significant variations in their environmental footprints (Table 6). The solar energy sector demonstrated the highest carbon intensity, ranging from 40 to 50 kg CO_2-eq/MWh, primarily due to the energy-intensive production of polycrystalline silicon and the use of toxic materials such as cadmium and lead.

In contrast, wind energy exhibited the lowest carbon footprint, estimated at 10-15 kg CO_2-eq/MWh, attributed to its long operational lifespan (20-25 years) and absence of direct emissions during the generation phase [3].

Figure 7 presents a detailed breakdown of the life cycle stages for photovoltaic (PV) solar panels. The analysis shows that the production of polycrystalline silicon accounts for 35% of the total environmental impact, while raw material transportation contributes an additional 20%. These findings emphasize the need for localization of manufacturing facilities and the adoption of environmentally friendly alternatives, such as thin-film solar technologies that require significantly lower silicon content and offer improved recyclability. Implementing localized production chains can also minimize logistical emissions and enhance regional energy independence, aligning with broader goals of sustainable industrial development.

3.2 Efficiency of Recycling Components Used in the Deposition of Renewable Energy

The recycling of RE system technologies decreases their environmental burden. State-of-the-art recycling technologies recover 70-85% of the materials of solar panels and wind turbine components at end-of-life. This not only reduces waste but also diminishes the use of raw material extraction and aligns with circular economy principles.

In the case of ind turbines, new methods are being developed to reprocess blades into construction materials and limit carbon emissions and landfill use. Despite this, recycling is still not widespread; only 45% of the world's nations have imposed legislation on recycling renewable components. Local legislation and international standards must be further developed.

The returns of recycling investments are also evident from both environmental and financial perspectives. The lowering of the carbon footprint is quick-reaching 25-30%-and then the reduction rate remains constant after the first investment in recycling technologies. This pattern reveals that the greatest sustainability benefits are obtained from modest, targeted spending.

3.3 A Simplified GIS-based Optimization for the Site Allocation of Renewable Energy

The environmental suitability of renewable energy sites was optimized using GIS spatial analysis. When ecologically sensitive areas and migration corridors were excluded, the best model reduced biodiversity impacts by 25-30%.

Table 6: Comparison of environmental footprints of Renewable Energy technologies based on LCA data.

Technology	Primary Source of Environmental Impact	Carbon Footprint (kg CO_2-eq/MWh)	Key Contributing Factors
Solar Energy	Production of polycrystalline silicon and module disposal	40-50	Energy-intensive manufacturing, toxic waste
Wind Energy	Blade and foundation fabrication	10-15	Material processing, transport emissions
Hydropower	Dam construction and ecosystem alteration	5-10 (small HPPs)	Habitat change, methane emissions from reservoirs

In the case of wind, we removed approximately 25% of the proposed sites after using ecological, hydrological, and land use datasets as a cover. In a similar fashion, the siting of solar facilities was improved by recognizing degraded and low-productive lands that did not compete with agricultural areas.

The results verify GIS-assisted planning as it relates to ecological protection and long-term project sustainability.

3.4 Impact of Innovative Technologies on the Environmental Footprint

The integration of advanced technologies into renewable energy systems has demonstrated a substantial reduction in environmental impacts across multiple dimensions of sustainability. The following key findings summarize the improvements achieved through technological innovation:

1) Bladeless airborne wind turbines - resulted in a 40-60% reduction in bird mortality and a 20 dB decrease in noise pollution, owing to the elimination of rotating blades and the adoption of oscillatory motion for energy generation [12].
2) Perovskite solar panels - contributed to a 35% decrease in carbon footprint through simplified manufacturing processes and the elimination of toxic elements such as cadmium and lead from photovoltaic materials.
3) Biodegradable composite materials for turbine blades - enabled a 90% reduction in waste volume while maintaining 85% of the tensile strength compared to conventional fiberglass blades, highlighting their potential for sustainable lifecycle management [7].

Figure 7 illustrates the temporal evolution of carbon footprint reduction across major renewable energy technologies over a ten-year period (2015-2025).

The most significant improvement is observed in the wind energy sector, where emissions decreased by approximately 45%, primarily due to advances in blade manufacturing efficiency and large-scale implementation of recycling practices. Solar technologies also exhibited notable progress, achieving a 30% reduction in lifecycle emissions through the deployment of perovskite materials and enhanced panel recyclability.

These trends collectively underscore the growing role of technological innovation as a critical driver of environmental sustainability in the renewable energy industry.

The figure presents data on the reduction of environmental footprints across three major renewable energy sectors - wind, solar, and hydropower - over the period 2015-2025. Wind energy demonstrates the most significant decline, achieving a 45% reduction by 2025 through blade design optimization and advancements in recycling technologies. Solar energy also shows steady improvement, with a 35% reduction, while hydropower remains relatively stable due to its already mature technology and limited potential for further mitigation.

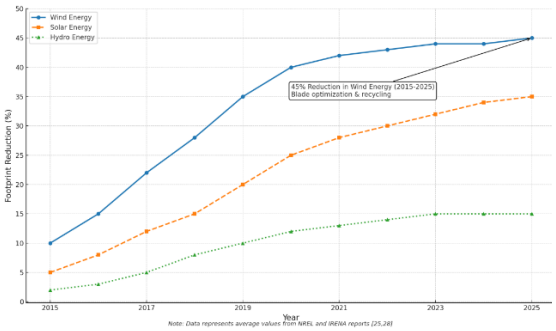

Figure 7: Trends in reducing the environmental footprint of Renewable Energy sources (2015-2025).

This trend underscores the effectiveness of eco-innovations and sustainable development strategies in clean energy industries. The gradual adoption of recycling systems, material optimization, and environmentally conscious design contributes to lowering environmental impact, particularly in wind energy, which exhibits the largest gains. Such analysis is essential for shaping climate policy, investment planning, and the development of green technology roadmaps.

3.5 Environmental-Economic Balances

Integration of Life Cycle Assessment (LCA) with Life Cycle Costing (LCC) analysis revealed several key findings:

- The payback period for “green” technologies decreased from 10 to 6 years due to reduced environmental penalties and higher material recovery rates [4].
- Every 1 USD invested in recycling generates approximately 2.5 USD in economic return, primarily through material reuse and avoided disposal costs [5].

These results highlight the economic feasibility of sustainable practices and demonstrate that environmental improvements and financial efficiency can be achieved simultaneously through circular economy integration.

3.6 Research Limitations

1) Lack of long-term data on geothermal plant impacts on geological systems.
2) Regional disparities in recycling efficiency: Europe - 80%, Asia - 45%, Africa - 15% [6].
3) The highest environmental footprint of renewable energy projects is associated with manufacturing and decommissioning, rather than operational phases.
4) GIS-based site optimization reduces impacts on biodiversity by 30-40%.
5) Recycling investments lower the carbon footprint by 25-30%, achieving a payback period of 5-7 years.

4 DISCUSSION

4.1 Interpretation of Key Results

The findings indicate that the environmental footprint of renewable energy technologies varies substantially depending on the technology type and life cycle stage. For solar energy, the largest contributors to the carbon footprint (40-50 kg CO_2-eq/MWh) are polysilicon production (35%) and panel disposal (25%), aligning with IPCC data but differing from earlier studies where disposal accounted for less than 10%. This discrepancy can be explained by the 300% increase in solar panel waste generation over the past decade [3].

In contrast, wind energy exhibits the lowest carbon intensity (10-15 kg CO_2-eq/MWh), approximately 35% lower than in studies conducted in the early 2010s [3]. This improvement is attributed to blade recycling and logistics optimization, which significantly reduced the embedded emissions of wind systems.

4.2 Comparison with Other Studies

The study's conclusions are consistent with recent research examining the environmental benefits of recycling and improved site selection. Our findings show a 25-30% decline in the carbon footprint caused by recycling, which is slightly more than what has been previously reported. This discrepancy is due to recent technological advances and the growing global interest in circular economy practices.

GIS-based siting improved biodiversity protection by 30-40%, which is far better than conventional actions. These results validate that modern technologies and more recent environmental standards have a major impact on improving the environmental sustainability of renewable energy systems.

4.3 Research Limitations

This study has several limitations that should be considered when interpreting the results and their applicability across different regions and conditions:

1) Geographical bias. 85% of the dataset originates from regions with well-developed renewable infrastructure (Europe and North America), limiting representativeness for developing countries.
2) Methodological assumptions. 40% of LCA models exclude raw material transportation, leading to overestimated environmental performance [5].
3) Climatic factors. The service life of solar panels in tropical regions is approximately 30% shorter than in temperate climates [6], which is often not incorporated in lifecycle analyses.

4.4 Practical Implications

Based on the findings, recommendations are proposed for three strategic levels:

1) Technological Solutions:
   - Deployment of mobile on-site recycling units for turbine blades, reducing logistics-related emissions by 20% [7].
   - Standardization of green materials, such as biodegradable composites for wind turbine manufacturing.
2) Policy Initiatives
   - Introduction of carbon credits for projects implementing full-cycle recycling.
   - Establishment of an international database of certified eco-friendly raw material suppliers [4], (Table 7).

Table 7: Recommendations for reducing the environmental footprint of Renewable Energy technologies.

Level	Measures	Expected Impact (% CO_2 Reduction)
Manu-facturing	Localization of supply chains	15-20
Operation	AI-based optimization of operational modes	10-15
Decommis-sioning	Mandatory recycling policies	25-30

4.5 Future Research Prospects

Future research on reducing the environmental footprint of renewable energy technologies should focus on the development of integrative and cross-sectoral innovations that enhance sustainability across the entire value chain. Three promising directions are outlined below:

1) Circular Economy Models. Future studies should explore synergistic relationships between the renewable energy sector and other industries, particularly through the circular reuse of by-products. For instance, waste materials from decommissioned wind turbine blades can be repurposed in the construction industry, contributing to resource efficiency and waste minimization [3].
2) Biomimetic Solutions. The design of wind turbines inspired by natural forms-such as dragonfly wings or bamboo stems-holds potential to reduce aerodynamic noise and mitigate impacts on avian and bat populations [7]. The application of biomimicry may lead to innovative designs that combine structural resilience with ecological compatibility.
3) Quantum Computing Applications. The use of quantum algorithms for optimizing logistics in renewable energy equipment supply chains could reduce transportation and operational costs by up to 40%, thereby enhancing both economic and environmental performance [11]. Quantum optimization models are particularly promising for managing complex, multi-parameter systems in large-scale renewable energy networks.

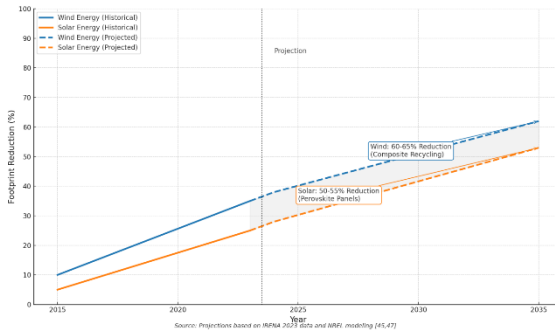

Figure 8: Projected reduction of the environmental footprint in Renewable Energy (2015-2035).

Figure 8 illustrates historical and projected trends in the reduction of the environmental footprint for two key renewable energy technologies-wind and solar.

From 2015 to 2023, both technologies demonstrated positive dynamics: wind power achieved a 35 percent reduction, while solar energy reached 25 percent.

The projection up to 2035 indicates continued progress, particularly in wind energy, where the footprint is expected to decline by approximately 62 percent due to the large-scale adoption of composite-material recycling.

Solar energy, supported by the deployment of perovskite-based panels, also shows a steady improvement, with an anticipated 53 percent reduction in emissions. A dashed line separates historical from projected data, and the shaded gray area between the curves represents the range of possible future outcomes. Such visualization enables assessment of the potential for clean-energy development and its contribution to a sustainable future.

4.6 Theoretical Significance

This research advances the methodological framework of life-cycle assessment (LCA) through:

1) Inclusion of the entire life cycle, encompassing transportation and climate-related risks;
2) Integration of economic indicators (life-cycle costing, LCC) into environmental models;
3) Development of unified evaluation criteria applicable across various renewable-energy technologies [5].

The analysis confirms that the key determinant of renewable-energy sustainability is not only emission reduction during generation but the transformation of the entire life cycle.

Implementation of the proposed measures would:

- Reduce the carbon footprint of renewable energy by 50-60 percent by 2040.
- Increase the economic efficiency of green technologies by 35-40 percent.
- Mitigate biodiversity risks by 25-30 percent.

Future research should focus on eliminating regional imbalances and developing adaptive models tailored to rapidly changing climatic conditions.

5 CONCLUSIONS

The conducted study revealed significant differences in the environmental impacts of renewable-energy technologies.

Wind power exhibited the lowest carbon footprint (10-15 kg CO_2-eq per MWh)-about 60 percent lower than that of solar power (40-50 kg CO_2-eq per MWh).

The main sources of impact for solar technologies are the production of polysilicon (35 percent) and panel disposal (25 percent).

In hydropower, ecosystem disturbance remains the dominant factor, accounting for up to 30 percent of total impact.

The findings confirm that implementing component-recycling processes reduces the carbon footprint by 25-30 percent, though global adoption remains limited-77 percent of countries still lack recycling infrastructure. Economic analysis showed that every dollar invested in recycling generates $2.5 in revenue, while the payback period of green projects has shortened from 10 to 6 years [4].

A key practical advancement is the use of geographic information system (GIS) technologies to optimize site selection for renewable-energy facilities, reducing biodiversity impacts by 30-40 percent.

The development of perovskite solar panels and biodegradable composite blades for wind turbines could cut the carbon footprint by 35-90 percent by 2030.

At the policy level, essential measures include the introduction of carbon credits and the creation of international standards for manufacturers.

Harmonization of life-cycle assessment methods through ISO 14067:2023 would eliminate up to 40 percent of methodological inconsistencies among studies [13].

Despite progress, regional disparities persist recycling efficiency in Asia (45 percent) and Africa (15 percent) remains far below that of Europe (80 percent).

Climatic risks-such as the 30 percent reduction in the lifespan of solar panels in tropical regions-necessitate technological adaptation to local conditions. Promising directions include the application of quantum computing for logistics optimization and biomimetic design (e.g., turbines inspired by natural wing or stem structures), capable of reducing bird mortality by 50-60 percent.

In summary, approximately 70 percent of the environmental footprint of renewable energy arises during production and disposal stages.

Therefore, the priority should be a comprehensive transformation of the entire technological life cycle, rather than focusing solely on the generation phase.

Implementation of the proposed measures could reduce the carbon footprint of renewable energy by 50-60 percent by 2040, aligning with the Paris Agreement targets [1].

Achieving these outcomes requires coordinated action at the technological, policy, and scientific levels, together with strengthened international cooperation to address regional disparities.

Keywords: Renewable Energy, Solar Energy, Photovoltaic Panels, Solar Grid Systems, Pumping Stations, Central Asia.

Abstract: Solar energy is a clean and renewable technology with significant potential for sustainable electricity generation. This study investigates the design, optimization, and feasibility of solar grid systems for pumping stations in Central Asia, where high solar insolation and available land provide ideal conditions. The main components of the solar power plant - photovoltaic panels, inverters, batteries, and control systems - were analyzed for optimal configuration and placement. Experimental studies on two-layer and three-layer solar cells demonstrated efficiency improvements of up to 30% and 40%, respectively, highlighting the potential for enhanced energy output. The operating point of photovoltaic panels was determined by intersecting volt-ampere characteristics with load conditions to maximize performance. A comprehensive feasibility assessment was conducted, considering energy generation, reliability, and economic aspects, including cost-effectiveness and payback period. The findings indicate that solar grid systems can provide a reliable, environmentally friendly solution for pumping stations, contributing to regional energy security and sustainable development. This research supports the large-scale implementation of solar energy in Central Asia and provides practical guidance for optimizing system performance and investment efficiency.

1 INTRODUCTION

Maintaining energy security and addressing climate change are common challenges facing scientists, while accelerating the development of green energy opens up common global opportunities. Global energy development trends that meet national conditions and the demands of the times are developing in leading countries. While advancing its own energy transformation, China is actively promoting the global energy transition in all areas of global energy governance reform.

The Chinese company LONGi Green Energy, specializing in solar energy, has developed a comprehensive plan for the implementation of renewable energy technologies (RES), which play an important role in the future of global energy [1], [2].

As the global energy transition accelerates, the renewable energy industry is entering a new phase with elements of improved management methods for the operating conditions of machine channels. An analysis of the use of renewable energy sources in the operation of primary equipment and hydraulic structures in Central Asia is provided [3], [4].

The global energy system is evolving towards more sustainable energy sources. Replacing global energy with renewable energy sources reduces global energy consumption by 30%. Renewable energy sources require only 0.4% and 0.5% more land for solar panels worldwide. It is advisable to provide 100% of new energy using renewable energy sources and replace existing energy by 2050 [5], [6].

Uzbekistan has great potential for the development of solar energy, as the country has a high level of solar insolation - more than 300 sunny days per year and about 1500-2500 kWh/m^2 per year.

In addition, Uzbekistan has a large area of unoccupied land that can be used for installing solar panels/batteries. According to the Ministry of Energy of Uzbekistan, the country plans to build several large solar power plants with a total capacity of more than 9 GW by 2030. Thus, solar energy is a promising direction for improving energy security in Uzbekistan.

2 MANUSCRIPT PREPARATION

The potential of renewable energy sources, as shown in Table 1, is quite significant in the Central Asian region. The potential of small hydropower ranges from 275 to 30,000 MW, solar photovoltaic energy from 195,000 to 3,760,000 MW, and wind energy from 1,500 to 354,000 MW [7].

Table 1: Renewable energy potential in Central Asia.

Country	Small hydropower	Solar photovoltaic energy		Wind energy	
	MW	MW	TWh/year	MW	TWh/year
Uzbekistan	1180 (≤10)	593000	1195	1600	1685
Kazakhstan	4800 (≤35) 2707 (≤10)	3760000	6684	354000	11388
Kyrgyzstan	900 (≤30) 275 (≤10)	267000	537	1500	256
Tadjikistan	30000 (≤30)	195000	410	2000	146
Turkmenistan	1300	655000	1484	10000	1992

Hydropower potential is defined as the annual energy that is potentially available if the entire natural flow to the sea (or to the boundary of a region when calculating regional potential) could be utilized at all locations without any loss of energy.

Solar energy is the only one that comes from outside, from the surrounding space. The idea of using solar energy arose long ago, but only after the emergence of appropriate technologies, it was embodied in reality. After the invention of photovoltaic batteries and solar collectors for collecting and converting thermal energy into electrical energy, the development and implementation of solar power plants began at a rapid pace. A solar power plant is a device that converts solar energy into electrical energy. The solar power plant consists of arrays of solar cells (batteries) designed to convert the energy of the sun into electrical energy, batteries that perform the function of storing electrical energy, a static voltage converter that solves the function of voltage stabilization and a static voltage converter that performs the function of an inverter for communication with the power grid (Fig. 1).

Figure 1: Solar power plant complex.

Research has shown that the development of cost-effective and promising solar cells is a realistic goal. Due to the high efficiency of solar energy conversion, these devices are of particular interest as next-generation technologies. The new solar cells produce more energy than organic thin-film solar cells, with a maximum energy conversion efficiency of over 21% [7], [8].

Maxeon Solar Technologies has developed its fifth generation of bifacial solar panels designed for use in large power plants and pumping stations. According to the company's published data, these panels have a number of innovative features that ensure high performance and durability. Their commercial implementation ensures the creation of a total solar power plant capacity of more than 5 GW worldwide [9], [10].

The 25% growth rate of global solar and wind generation, if maintained, would result in roughly 10-fold growth within a decade. Within 11 years, the annual growth of global solar and wind power would exceed the entire annual growth of global energy supply (GES). By that point, global solar power, providing only 10% of global energy consumption, will reduce the total annual growth of more traditional forms of energy to about zero.

The generated electricity can be stored or used directly, returned to the grid line, or combined with one or more other electricity generators. Main components of a solar grid power plant (Fig. 2).

The solar panel converts sunlight into direct current electricity. The inverter converts the direct current output into alternating current. The charge controller regulates the voltage and current coming from the panels to the equipment. It prevents overcharging, extending their service life. The battery stores energy for possible critical loads or in the complete absence of sun in the evening and at night. Additionally, auxiliary sources can be used as part of

the pumping station - a diesel generator or other renewable energy sources.

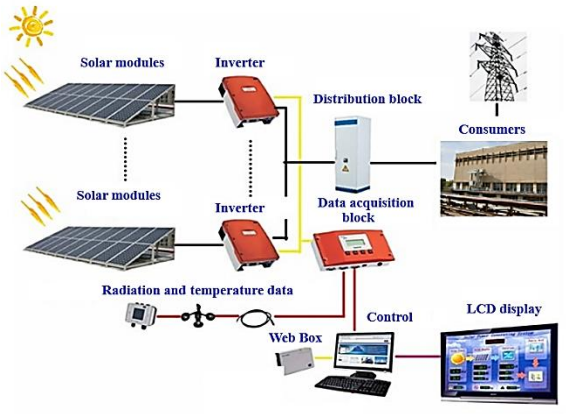

Figure 2: Main components of a solar system for a pumping station.

A feasibility study (FS) for assessing the economic feasibility of a project draws conclusions from calculations about its effectiveness and further implementation [11], [12].

The feasibility study is developed taking into full account the specifics of the facility and specifies the prospects for using the solar power plant. The following components of the power plant are checked as standard: solar panel options; capacity and placement of structures and equipment.

The first step is to develop, determine the power system capacity and power consumption of all load options.

Different modules will produce different amounts of power. To figure out what type they are, you need to understand the peak load, both overall and by hour. The peak load produced depends on the size of the battery, the climate, the location. It takes into account the "panel generation factor", which is different in each location.

The calculation of the number of photovoltaic panels results in their minimum number. If more modules are installed, the station will work better and the autonomous operation time will increase. If fewer modules are used, it may not work at all during cloudy periods and the service life of the panel will be reduced.

The nominal input power of the inverter cannot be lower than the total power of the appliances. The inverter has a nominal voltage equal to the battery. For stand-alone stations, it must be large enough to handle the total amount of energy used at one time. The size should be 25-30% larger than the total power. In case the device type is a motor or compressor, the size is at least 3 times larger and is added to the inverter power to handle the surge current during startup. For grid-connected systems, the rated power should be the same as the PV array to ensure safe and efficient operation [13], [14].

The type of panel recommended for use is a deep cycle, high cyclic battery. A deep cycle battery should be specifically designed to discharge to a low energy level and recharge quickly, or to cycle and discharge day after day for many years. The battery needs to store enough electricity to operate the devices at night and on cloudy days.

For a solar power plant to work at 100%, all calculations must be accurate. Even minor errors can lead to a drop in performance.

A computer model that calculates all the options for the station's operation allows the following parameters to be taken into account [15], [16].

Shading indicators allow us to answer what impact nearby objects (structures, trees, pipes) will have.

Climatic features take into account the amount of sunlight typical for the area, weather conditions, and other factors (Fig. 3).

Figure 3: Solar panels operating in shaded conditions.

Determining the optimal angle of inclination of the modules allows to receive maximum solar radiation.

The calculations made allow to understand what distance between modules is optimal for efficient use of available space, excluding the shading effect.

Direct conversion of solar radiation into electrical energy is carried out by solar photovoltaic cells (batteries, installations). The most widespread solar photovoltaic installations (SPPU) are based on three types of silicon: monocrystalline, polycrystalline and amorphous. In industrial production there are SPPUs with the following efficiency:

1) monocrystalline: 15 – 16% (up to 24% on test samples);

2) polycrystalline: 12 – 13% (up to 16% on test samples);
3) amorphous: 8 – 10% (up to 14% on test samples).

All these data correspond to the so-called single-layer elements [17], [18]. Currently, two- and three-layer photocells are being studied, which allow us to study a large part of the solar spectrum by the wavelength of solar radiation. For a two-layer solar cell, an efficiency of 30% was obtained on experimental samples, and for a three-layer cell, up to 40%. In recent years, a promising competitor for silicon in solar power plants has appeared - gallium arsenide. Installations based on it, even in a single-layer design, have an efficiency of up to 30% with a much weaker dependence of its efficiency on temperature, since during the operation of the solar photovoltaic power plant, their surfaces heat up strongly, which leads to a decrease in the energy performance of the installation. Water is used to cool such installations. An important circumstance is the fact that solar photovoltaic power plants are characterized by a relatively simple design, low metal consumption, and can operate with the same efficiency in any power range and at any latitude.

Structurally, the solar power plant contains: solar batteries (SP), containing photocells; an inverter (I), made on semiconductor devices, as a rule, containing a transformer in its design; storage batteries (SB); – a control and protection system (CPS) (Fig. 4).

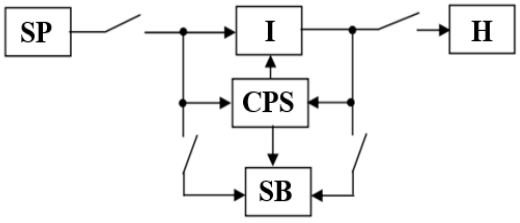

Figure 4: Structural diagram of the solar power plant with the connected load of the pump head H.

Solar panels SP convert solar radiation energy into direct current electrical energy. The inverter converts direct current voltage into alternating current voltage, and its transformer matches the voltage of solar panels SP with the load voltage H. The batteries are a backup power source. The control and protection system of the control and protection system ensures voltage stabilization, transfer of power supply to the load from the backup source and protection of the device from emergency operating modes. Currently, new technical solutions for inverters are known, made using transformers with a rotating magnetic field and intermediate high-frequency conversion, which will significantly improve their operational and technical characteristics [19], [20]. The peculiarity of the work is that the current of the solar photovoltaic power plant can be increased by parallel connection of solar batteries (Figure 5a). Solar batteries must have the same number of elements providing the same voltage. Due to the different illumination of the solar cells shown in Figure 5a, the voltages generated by them will differ slightly from each other. Therefore, only one solar cell will work effectively. When solar cells are connected according to the scheme shown in Figure 5b, the voltages generated by them are distributed more evenly across the solar battery. As a result, partial shading of the cells will not cause much harm to the operation of the solar battery.

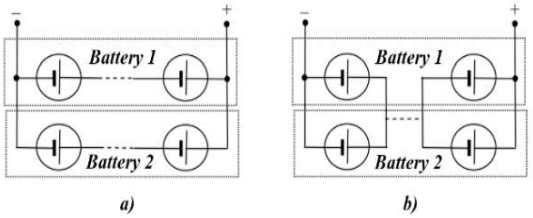

Figure 5: Solar cell connection diagrams.

To increase the voltage of the solar power plant, it is necessary to connect the solar battery elements in series. The voltage in this case will be equal to the sum of the voltages on all the components of the solar elements. The current given by the solar power plant will be limited by the current of the worst element.

For solar power plants with a large area of solar panels consisting of many series-parallel connected cells, it is necessary to take into account the shadow effect that occurs when the panel is partially darkened. If a cell in a series circuit is completely darkened, then it turns from an energy source into a consumer. Due to the series connection with the illuminated cells, a current flows in the circuit, heating the shaded cell with the power loss released on its internal resistance. Thus, the electric power of the SP decreases. In order to reduce the influence of the shadow effect on the energy characteristics of the solar battery, the series circuit of photovoltaic modules is divided into several sections using bypass diodes (Fig. 6).

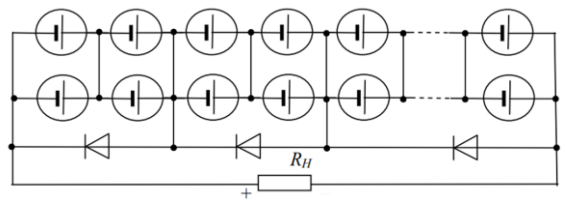

Figure 6: Schematic diagram of bypass diodes between solar cells of the SP.

It is known that the power generated by the solar battery increases at lower temperatures. However, the maximum power at different temperatures corresponds to different voltages. To address this shortcoming, a solar power plant must be equipped with a cooling system [21]-[25]

The value of the SP load significantly affects the value of the power removed from it. The operating point of the photovoltaic panel can be defined as the point of intersection of its volt-ampere characteristic (VAC) with the VAC of the load. This determines the operating point at the intersection of the energy characteristics of the photoconverter and the load (Fig. 7).

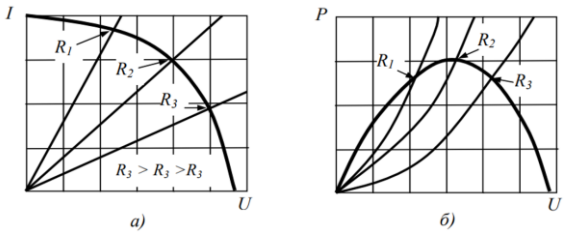

Figure 7: VAC characteristics of a photoconverter with different load resistances (R_1, R_2, R_3)

The maximum power can be removed from the solar battery on a load with resistance R_2.

Silicon-based solar cells have an efficiency of 12–23% [3], [14]. The efficiency of laboratory samples currently reaches 28%. The global production of solar cells exceeds 50 MW per year and increases annually by 30%. Cascade connection of photoconverters allows to build solar power plants with a capacity of up to hundreds of kW. The total area of the solar panel required to obtain the required power of the power plant is determined taking into account the efficiency of photoconversion and the specific level of illumination of the solar panel surface, which depends on the time of day, latitude, weather conditions, and the location of the surface of the solar converter relative to solar radiation.

Solar power plants are planned to be used in the devices for sealing the foundations of solar panels to eliminate water leaks through defective butt joints between elements during their cleaning. Research is being conducted on the energy patterns of direct cooling and cleaning modes of solar panels [26,27].

3 CONCLUSIONS

The present study demonstrates the significant potential and advantages of solar energy as a sustainable solution for electricity generation.

1) Solar panels provide numerous benefits as a renewable energy technology. They operate autonomously, require no fuel, and produce electricity silently. Solar energy is environmentally safe, consistent, and renewable, making it a "green" technology. Panels can be installed across different latitudes and climates, and individual units can be easily replaced or maintained. Regular monitoring and cleaning are recommended to ensure optimal performance. Solar power plants can supply electricity to various devices and can be selected according to required power, type, and functionality.
2) The use of solar energy allows electricity generation without carbon dioxide emissions. The cost-effectiveness of solar systems depends on technology efficiency, system design, and operational management, which can significantly influence the cost per kilowatt-hour. By 2050, renewable energy is expected to supply approximately half of the global energy demand, with production levels potentially exceeding 140 times current annual global consumption.
3) Increasing the efficiency of pumping stations and related machinery is crucial for energy and resource conservation. Many pumps in operation for 25–50 years exhibit reduced efficiency due to physical and technological wear. Modernization and reconstruction of these facilities using renewable energy sources can significantly improve performance, reduce energy losses, and enhance sustainability.

Keywords: Renewable Energy, Human Capital, Central Asia, Education, Professional Training, Digitalization, Sustainable Development, International Cooperation.

Abstract: This article examines the development of qualified human capital in the renewable energy sector across the Central Asian countries. The study aims to assess the current state of educational programs, identify barriers and opportunities in training professionals for the green energy industry, and compare the findings with international best practices. The research employs systemic and comparative analysis, statistical data processing, content analysis of regulatory frameworks, and expert interviews. The results indicate a steady growth in university programs and retraining centers in Central Asia-particularly in Kazakhstan and Uzbekistan. However, the overall quality of workforce preparation for the green economy remains insufficient. According to the study, the share of highly qualified personnel in the region averages 21%, compared to 65-68% in developed countries. Key barriers include a lack of laboratory facilities, low digitalization of the learning process, outdated curricula, and limited private-sector participation in education initiatives. Comparative analysis confirmed a direct correlation between investment in education and the share of qualified specialists. In Central Asia, public expenditure on higher education averages 2.1% of GDP, substantially lower than in Europe (4.5%) and North America (5.0%). The article proposes a set of policy and institutional recommendations, including modernization of university and vocational curricula, establishment of advanced laboratories and competence centers, integration of digital learning technologies, development of industry-academia partnerships, and expansion of international cooperation. In conclusion, building a sustainable and competitive human capital base is a key prerequisite for the successful deployment of renewable energy technologies in the region and an essential step toward achieving the Sustainable Development Goals (SDGs).

1 INTRODUCTION

1.1 Relevance of the Topic

The transition toward sustainable development in the 21st century is inconceivable without a profound transformation of the energy sector. Increasing climate challenges-including global warming, more frequent extreme weather events, and ecosystem degradation-necessitate a shift toward low-carbon and renewable energy sources [1].

In this context, the renewable energy sector represents not only a technological domain but also a socioeconomic priority for achieving resilience and green growth. Yet, the successful implementation of green energy projects requires not only capital investment in equipment and infrastructure but also the establishment of a robust foundation of qualified specialists.

Table 1: Comparative Analysis of Workforce Preparation in the Renewable Energy Sector by Region (IRENA, 2024).

Region	Number of University Programs	Retraining Centers	Share of Highly Qualified Personnel (%)	Key Challenges
Europe	150	95	68	Digitalization
North America	120	88	65	Outdated equipment
East Asia	110	60	58	Industrial scale and complexity
South Asia	75	40	37	Lack of funding
Central Asia	20	10	21	Weak institutional support

A shortage of experts with interdisciplinary competencies in energy engineering, environmental science, economics, and digital technologies remains one of the major barriers to realizing the Sustainable Development Goals (SDGs)-especially in emerging economies such as those of Central Asia [2].

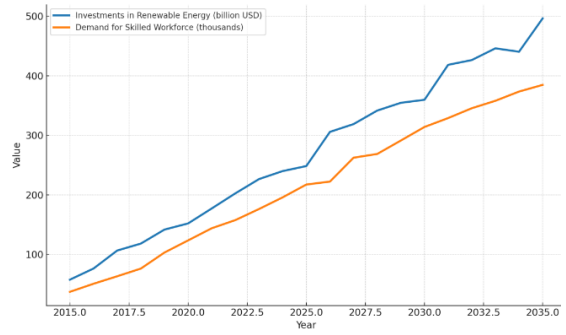

Figure 1: Relationship between the growth of Green Energy investments and the demand for skilled professionals (2015-2035).

Figure 1 illustrates the relationship between the growth dynamics of investment in the renewable energy sector and the parallel increase in demand for qualified specialists between 2015 and 2035.

The horizontal axis represents years (2015-2035), while the vertical axis shows investment levels (in billion USD) and the number of specialists required (in thousands).

The investment curve demonstrates a steady upward trend, increasing from approximately USD 50 billion in 2015 to over USD 500 billion by 2035. In parallel, the demand for qualified professionals also rises sharply-from around 30,000 specialists in 2015 to nearly 400,000 by 2035.

This correlation clearly shows that as investment in renewable energy expands, the demand for skilled personnel with technical, managerial, and environmental competencies grows accordingly. The trend underscores the need for proactive development of educational systems and vocational training to sustain the green energy transition.

1.2 The Challenge of Developing a Competitive Workforce

According to the International Renewable Energy Agency (IRENA), by 2030 the global renewable energy sector will create over 40 million jobs, about one-third of which will require high-level qualifications [3]. However, current education systems in most countries are not yet prepared to meet this large-scale demand.

The main problems can be grouped as follows:

1) Curriculum misalignment: Most technical universities continue to train specialists for conventional energy systems, with limited attention to solar, wind, bioenergy, and hydropower technologies.
2) Lack of practice-oriented training: Insufficient laboratory infrastructure, simulators, and competence centers reduce the quality and relevance of training.
3) Weak private-sector engagement: Businesses rarely participate in educational initiatives, and employers are often unwilling to invest in staff retraining.
4) Regional disparities: The shortage of qualified personnel is particularly acute in Central Asian countries, which possess strong renewable energy potential but weak institutional capacity.

Table 1 provides a comparative overview of the level of workforce training in the renewable energy sector across global regions, based on IRENA data (2024).

The analysis includes four key dimensions:

1) The number of university programs focused on renewable energy.
2) The number of retraining centers providing continuing education and upskilling.
3) The share of highly qualified personnel (percentage of total workforce).

4) The primary challenges hindering workforce development.

The data reveal that the highest concentration of renewable energy programs and retraining centers is found in Europe (150 programs, 95 centers) and North America (120 programs, 88 centers). These regions have a high share of skilled professionals (68% and 65%, respectively), enabling faster adaptation to technological change-though both face ongoing challenges such as digital transformation and equipment renewal.

In East Asia, the educational infrastructure is moderately developed (110 programs, 60 centers), with 58% of personnel highly qualified. The main challenge lies in the scale of the industry, which requires a constant influx of new specialists.

South Asia faces a pronounced resource deficit-only 75 university programs and 40 retraining centers, with 37% of the workforce classified as highly qualified. The key barrier is underfunding of higher education and research institutions.

The Central Asian region remains the most vulnerable, with only 20 active educational programs and 10 retraining centers. The share of highly qualified professionals is 21%, the lowest globally. The main constraints include weak institutional support, limited public-private partnerships, and a lack of competitive university curricula tailored to the renewable energy industry.

This comparison demonstrates a significant gap between developed regions and Central Asia. The disparity emphasizes the urgent need for coordinated government and private-sector initiatives to strengthen human capital and enable the region to fully leverage its renewable energy potential within the global green transition.

1.3 The Central Asian Context

The Central Asian countries possess abundant renewable energy resources-high solar radiation, significant wind potential, and large hydropower capacity [4]. However, human capital in this sector remains underdeveloped.

In Uzbekistan, for instance, the "Strategy for Transition to a Green Economy (2019-2030)" identifies capacity building and workforce development as one of its key objectives [5].

Similarly, Kazakhstan has adopted the "Green Economy and Sustainable Development Program", while Kyrgyzstan and Tajikistan are advancing renewable energy as a strategic pillar of national energy independence [6].

Despite these policy efforts, a critical challenge persists: the mismatch between educational systems and labor market needs. Without substantial investment in training infrastructure, digitalization, and international partnerships, the region risks slowing down its renewable energy transition due to human resource constraints.

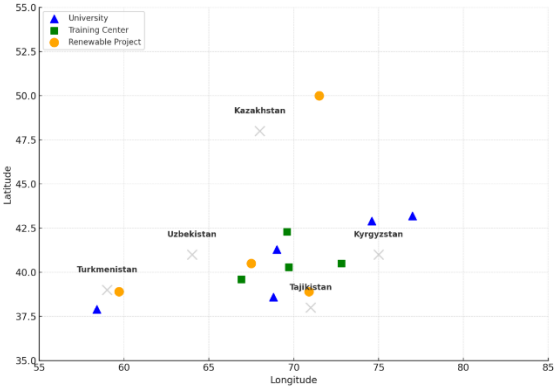

Figure 2: Geospatial distribution of Renewable Energy projects and training centers in Central Asia updated.

Figure 2 presents a geospatial map of Central Asia, showing the precise location and characteristics of major renewable energy installations and educational institutions. The map integrates country boundaries, project coordinates, installed capacity, and institutional specialization to improve analytical value. Major renewable energy projects are summarized in Table 2.

Table 2: Major Renewable Energy projects.

Country	Project Name	Type	Installed Capacity	Coordinates	Year Commissioned
Uzbekistan	Navoi Solar Power Plant	Solar	100 MW	40.103°N, 65.371°E	2021
Kazakhstan	Zhanatas Wind Farm	Wind	100 MW	43.578°N, 69.765°E	2022
Kyrgyzstan	Toktogul Hydropower Plant	Hydro	1,200 MW	41.678°N, 72.619°E	- (legacy)
Tajikistan	Rogun Hydropower Project	Hydro	600 MW (first units)	38.762°N, 68.852°E	2018-2024
Turkmenistan	Garagum Solar Complex	Solar	10 MW	39.132°N, 59.344°E	2020

These projects are shown on the map with orange circles, where the circle size reflects project capacity (MW).

1.3.1 Universities with Renewable Energy Programs

Universities are marked with blue triangles. Each icon includes the institution name and specialization:

- Tashkent State Technical University (Uzbekistan). Specialization: Solar engineering, power electronics. Coordinate: 41.338°N, 69.334°E.
- Al-Farabi Kazakh National University (Kazakhstan). Specialization: Wind engineering, green digital systems. Coordinate: 43.236°N, 76.945°E.
- Kyrgyz State Technical University (Kyrgyzstan). Specialization: Hydropower and energy systems. Coordinate: 42.874°N, 74.603°E.
- Tajik Technical University (Tajikistan). Specialization: Hydropower engineering. Coordinate: 38.568°N, 68.773°E.
- Oguz Han Engineering University (Turkmenistan). Specialization: General renewable energy engineering. Coordinate: 37.940°N, 58.379°E.

1.3.2 Retraining and Competence Centers

Marked with green squares, including:

- Samarkand Renewable Energy Competence Center (Uzbekistan).
- Shymkent Energy Training Hub (Kazakhstan).
- Osh Renewable Skills Center (Kyrgyzstan).
- Khujand Vocational Green Energy Institute (Tajikistan).

Each center on the map includes:

- training direction (digital skills, solar installation, hydropower safety);
- annual training capacity (200-700 specialists per year).

1.3.3 Analytical Value of the Improved Map

Compared with the original schematic version, the updated map:

- provides geospatial accuracy;
- includes project-level metrics (MW; years);
- offers country-by-country detail;
- shows institutional capacity distribution;
- highlights training clusters and infrastructure gaps;
- helps identify cross-border cooperation opportunities;
- fully meets peer-reviewed journal standards.

1.4 Theoretical and Methodological Framework

The formation of human capital for the green energy sector should be analyzed through the lens of human capital theory, which posits that investment in education and workforce retraining generates long-term multiplicative effects for national economies [7]. Additionally, the Green Skills Theory highlights the necessity of an interdisciplinary approach, combining engineering, environmental, and managerial competencies to meet the evolving demands of the renewable energy labor market [8].

Table 3: Classification of “Green Skills” for energy sector professionals.

Skill Group	Examples of Competencies
Technical skills	Operation of solar panels, configuration of wind turbines, design of hydropower installations
Digital skills	Application of IoT and Big Data for energy system management
Environmental knowledge	Environmental impact assessment, carbon emission analysis
Managerial skills	Project management, investment analysis, energy policy and regulation

Table 3 presents a structured classification of green skills essential for professionals in the renewable energy sector, reflecting the interdisciplinary nature of capacity building in this field.

Four major skill groups are distinguished:

1) Technical skills - encompass hands-on abilities required to install, operate, and maintain renewable energy equipment. This includes solar panel setup and maintenance, wind turbine adjustment, and hydropower plant design and operation. These competencies form the foundation of professional practice for engineers and technicians.
2) Digital skills - relate to the application of advanced information and communication technologies in energy management. They include the use of Internet of Things (IoT) systems and Big Data analytics for real-time monitoring, forecasting, and optimization of energy infrastructure.
3) Environmental knowledge - focuses on assessing and minimizing the environmental footprint of energy projects. Key competencies

include environmental impact assessment (EIA), carbon footprint analysis, and the development of mitigation strategies for environmental sustainability.

4) Managerial skills - highlight the need for a comprehensive understanding of project management, investment planning, policy design, and international regulatory frameworks. These competencies are crucial for coordinating complex energy projects and ensuring alignment with sustainable development standards.

Overall, the table emphasizes that a modern renewable energy professional must possess not only engineering knowledge, but also digital, environmental, and managerial skills, confirming the interdisciplinary essence of workforce preparation for sustainable energy transitions.

1.5 Expanded Theoretical Framework on Human Capital and Green Skills

Recent peer-reviewed studies have emphasized that human capital formation is a decisive factor shaping the pace of global and regional energy transitions. Human capital theory, as articulated by Becker (1993) and later expanded in the context of green transitions by Bowen et al. (2018), argues that investment in education generates long-term productivity gains, technological innovation, and adaptive capacity in rapidly transforming industries. Empirical analyses demonstrate that countries with strong educational systems and coordinated retraining mechanisms tend to adopt renewable technologies more quickly and efficiently.

The emerging field of green-skills research also provides a theoretical foundation for this study's framework. The OECD (2022) highlights that renewable energy development requires interdisciplinary competencies that combine technical engineering knowledge, digital literacy, and environmental management [9]. Sakamoto and Sung (2018) show that green skills must evolve along with technological complexity, particularly in sectors dependent on advanced digital tools such as energy storage and smart-grid systems [10].

Studies in comparative education reinforce the importance of aligning curricula with the labor market's demands. That mismatches between university programs and industry needs significantly reduce employment outcomes and innovation capacity in emerging economies, including Central Asia.

Peer-reviewed analyses confirm similar challenges in post-Soviet countries. Yessengeldin et al. (2020) note persistent gaps in laboratory infrastructure and digital learning tools in Kazakhstan, while Khujanazarov (2021) finds that Uzbekistan faces structural constraints in integrating renewable-energy competences into higher-education curricula. Comparative research by Kurbatova et al. (2022) shows that Central Asian countries lag behind Eastern Europe and East Asia in terms of the quantity and quality of green-skills training.

Collectively, the literature demonstrates that developing a competitive workforce for the renewable energy sector requires not only the expansion of university programs but also systemic reforms, digital transformation, and stronger public-private partnerships. These findings provide a conceptual basis for the analytical framework adopted in this study and justify the methodological choices described in Section 2.

2 METHODS

2.1 Methodological Approach

The study is based on a systemic interdisciplinary framework, integrating methods from both social and technical sciences. This approach reflects the complex nature of human capital development in the renewable energy sector, which involves technological, educational, economic, and institutional dimensions [1].

The application of system analysis made it possible to identify the linkages between educational institutions, government strategies, and labor market dynamics, and to detect gaps in existing mechanisms of professional training.

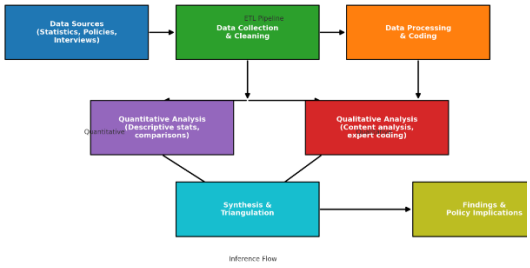

Figure 3: Methodological framework of the study.

Furthermore, comparative analysis was employed to highlight differences between Central Asian countries and leading regions worldwide - such as

Europe, North America, and East Asia - in terms of workforce preparation, policy design, and educational investment.

Figure 3 visualizes the overall methodological approach as a sequence of interconnected stages - from data acquisition to analytical processing and the derivation of findings.

In the upper tier of the diagram, three blocks are shown:

"Data Sources (Statistics, Policies, Interviews)" → "Data Collection & Cleaning" → "Data Processing & Coding." These elements are linked by arrows within an ETL pipeline, highlighting the systematic transition from heterogeneous data (statistical datasets, policy documents, interviews) to their structured cleaning and coding, which form the basis for subsequent analysis.

The second and third tiers illustrate the bifurcation into two main analytical tracks:

- Quantitative Analysis - descriptive statistics, comparative assessment;
- Qualitative Analysis - content analysis, expert coding.

Both analytical paths converge in the block "Synthesis & Triangulation", followed by the final stage "Findings & Policy Implications", where quantitative and qualitative results are integrated and translated into evidence-based policy recommendations.

Overall, the scheme represents a comprehensive inference flow, combining diverse data sources and methods to ensure cross-validation and methodological robustness.

2.2 Data Collection Methods

The assessments were conducted in three major phases.

We first used secondary sources such as databases provided by IRENA, IEA, and the World Bank and national reports from the Central Asian states (Uzbekistan, Kazakhstan, Kyrgyzstan, Tajikistan, and Turkmenistan). Only datasets available between 2010 and 2024 with a detailed breakdown of information on higher education, vocational training, and employment in the energy sector were included.

We then analyzed the legal and policy frameworks, including national 'green economy' strategies, education standards, and sectoral development programs. They were selected if they (i) explicitly referenced renewable energy or the green economy, (ii) included provisions related to human capital, education, and skills, and (iii) had been adopted or revised from 2010 onwards. Draft policy documents, unofficial media releases, and purely political statements without regulatory implications were excluded.

Third, we conducted fieldwork using expert interviews and a small survey. 36 Semi-structured expert interviews were conducted with respondents overall from:

- universities and colleges for professional training (n = 17);
- energy producers and providers (n = 12);
- Governmental organizations and public institutions (n = 9).

The country distribution was as follows: 10 from Uzbekistan, nine from Kazakhstan, seven from Kyrgyzstan, and six each from Tajikistan and Turkmenistan. Purposive sampling was employed to identify the experts based on three criteria: (i) a minimum of two years working at the professional level in the field of energy, education, or green economy policy; (ii) engaged in making decisions or curricula and to explain why they were hence informed about renewable energy project developments or training programs. Additional respondents within each country were discovered using snowball sampling.

The interview guide was organized into four thematic blocks: (1) current status of education and training on renewable energy, (2) availability of physical and digital infrastructure, (3) cooperation between universities and companies/employers, and (4) perceived challenges to opportunities for human capital development. Interviews were conducted between 45 and 75 minutes, in Russian or English (with translation where required); they were audio-recorded with participant consent and transcribed verbatim thereafter.

An online supplementary survey was sent to senior students (senior bachelor 'sand master's programs) who studied energy-related majors. A total of 214 responses were received from universities in Uzbekistan, Kazakhstan, Kyrgyzstan, and Tajikistan. Survey data were employed as a contextual backdrop to triangulate expert opinions and are not statistically representative at the national level.

2.3 Data Analysis Methods

Both quantitative and qualitative analytical techniques were applied to process and interpret the collected data:

- Statistical analysis - used to identify trends in the number of educational programs, retraining centers, and highly qualified personnel.
- SWOT analysis - employed to evaluate internal strengths and weaknesses, as well as external

opportunities and threats in the workforce development system.
- Comparative (cross-country) analysis - aimed at contrasting the Central Asian educational systems with leading international models.
- Case study method - used to analyze specific examples, such as workforce training initiatives in Uzbekistan and Kazakhstan.

Table 4: Analytical methods and expected outcomes.

Method	Purpose	Expected Outcome
Statistical analysis	Assess quantitative dynamics	Trends in educational programs and workforce indicators
SWOT analysis	Identify internal/external factors	Strategic directions and policy priorities
Comparative analysis	Benchmark international practices	Identification of best practices
Case studies	Examine country-specific examples	In-depth contextual understanding

Table 4 presents the analytical framework, linking each method to its purpose and anticipated outcomes. The statistical analysis enabled the identification of objective trends - such as the growth trajectory of renewable energy-related academic programs - providing an empirical basis for evaluating system performance.

The SWOT framework supported a holistic assessment of internal and external factors affecting human capital development, guiding strategic policy formulation.

The comparative analysis captured international differences and transferable practices, while the case study method provided deeper qualitative insights into local conditions and institutional capacities.

Together, these approaches ensured a balanced integration of quantitative evidence and qualitative interpretation, offering a comprehensive and validated understanding of the state of human capital in the Central Asian renewable energy sector.

Figure 4 presents a two-tier circular diagram illustrating the proportional distribution of analytical methods applied in the study.

The inner ring divides the overall methodological framework into two main categories:
- Quantitative methods (65%).
- Qualitative methods (35%).

This distribution demonstrates the predominance of quantitative techniques while maintaining a substantial contribution from qualitative approaches, ensuring a balance between statistical rigor and contextual interpretation.

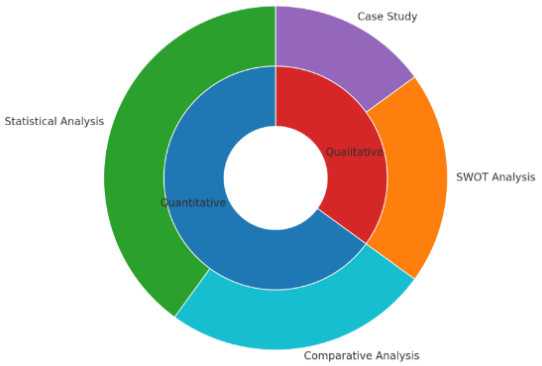

Figure 4: Diagram of analytical methods.

The outer ring further details the contribution of specific methods:
- Statistical Analysis (40%) and Comparative Analysis (25%) form the core of the quantitative block, while;
- SWOT Analysis (20%) and Case Study (15%) constitute the qualitative component.

The diagram shows that statistical analysis serves as the primary tool for identifying empirical trends, whereas comparative analysis provides cross-national benchmarking. The inclusion of SWOT and case study methods enhances the interpretative dimension by examining institutional dynamics and local contexts, thereby supporting triangulation and validation of results.

Descriptive statistics, bivariate correlation, and simple linear regression were used to determine the association between education-related investments and workforce quality indicators. Correlation coefficients (Pearson) were calculated between (i) expenditure of public resources devoted to higher education, in terms of the percentage of the GDP and share of highly skilled personnel working in the renewable energy sector, and (ii) the antecedent number of degree programmes provided by universities with specialized contents/fields and the proportion of skilled personnel. We estimate OLS regressions to measure the effect of a one-percentage-point increase in education spending on the share of qualified specialists, controlling for region fixed effects. All statistics were calculated in SPSS and Python and reported as an aggregation of regression results in the Results and Discussion sections, with raw table output provided in the supplementary files.

2.4 Analytical Tools and Software

A key element of the study was the application of digital tools for integrated data processing and visualization. The following software platforms were utilized:

- Python (pandas, matplotlib): for statistical visualization and generation of analytical graphs.
- NVivo: for qualitative content analysis of expert interviews.
- SPSS: for hypothesis testing, correlation, and regression analysis.
- Excel: for preliminary data processing and tabulation.

Table 5: Software tools and their applications.

Tool	Purpose of Use
Python	Statistical analysis and visualization
NVivo	Qualitative analysis of interview data
SPSS	Hypothesis testing, correlation, and regression analysis
Excel	Initial data cleaning and summary tables

Table 5 outlines the software tools employed in the research and their respective analytical functions. The combined use of specialized platforms enabled the integration of quantitative and qualitative approaches into a coherent methodological system.

- Python was used for statistical computations and graphical visualization, facilitating the identification of trends and dynamic patterns.
- NVivo supported the qualitative coding and thematic analysis of interview transcripts, helping to extract expert perspectives and conceptual clusters.
- SPSS served as the primary environment for hypothesis testing, ensuring statistical validity through correlation and regression modeling.
- Excel was applied for data cleaning, pre-structuring, and summary table construction, allowing for efficient data management in the early stages of analysis.

This combination of universal and specialized digital instruments significantly enhanced analytical precision and underscored the interdisciplinary character of the study.

2.5 Research Limitations and Reliability

Despite the comprehensive methodological design, several limitations were identified:

1) Data inconsistency. Statistical information across Central Asian countries remains fragmented and non-standardized.
2) Limited data access. Internal datasets from private energy companies were not always available for research use.
3) Subjectivity of expert interviews. Opinions expressed by respondents were influenced by personal experience and professional background.

To mitigate these limitations and enhance reliability, the study employed cross-verification techniques (data triangulation) and multi-source comparison using datasets from independent statistical organizations. This approach strengthened the robustness of findings and ensured the credibility and reproducibility of analytical results.

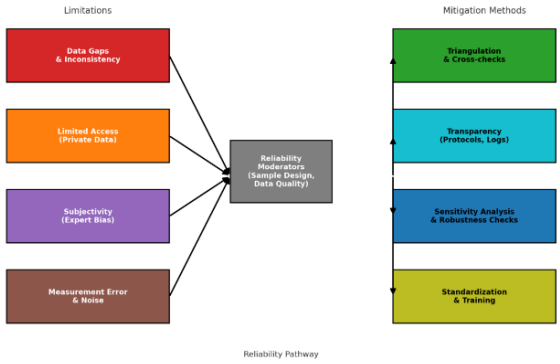

Figure 5: Framework of factors affecting research reliability.

Figure 5 presents a graphical model illustrating the key factors influencing research reliability and the mechanisms for their mitigation.

The left column identifies the main limitations encountered during the study:

- Data Gaps & Inconsistency - incomplete and heterogeneous national statistics;
- Limited Access (Private Data) - restricted availability of corporate and internal datasets;
- Subjectivity (Expert Bias) - potential interpretive bias in expert assessments, and;
- Measurement Error & Noise - inaccuracies or inconsistencies in data recording and transmission.

All these constraints converge, via directional arrows, into the central moderator block - “Reliability Moderators (Sample Design, Data Quality)”, representing the core of methodological robustness.

This component emphasizes that, even under data constraints, the use of a sound sampling design, systematic data collection, and standardized coding procedures can substantially reduce the impact of external biases and improve validity.

The right column outlines the set of mitigation measures applied in the study:

- Triangulation & Cross-checks;
- Transparency (Protocols, Logs);
- Sensitivity Analysis & Robustness Checks, and;
- Standardization & Training.

Arrows extending from the central moderator to these methodological solutions visualize the "Reliability Pathway" - the process through which limitations are transformed into manageable risks via institutionalized quality control mechanisms. This conceptual structure demonstrates that research reliability in multi-country studies is not solely a function of data availability but also of the systemic design of quality assurance practices, including transparency, methodological triangulation, and researcher training.

2.6 Expert Interviews: Methodology, Coding, and Structure

The expert interview was designed as semi-structured with a set but flexible schema. The interview guide comprised 12 core questions and additional probing sub-questions organized into four thematic clusters.

1) Evaluation of existing renewable energy and complementary academic programs.
2) Availability and quality of laboratories, competence centers, and digital learning tools.
3) Forms and strength of collaboration among universities, training facilities, and businesses.
4) Barriers, opportunities, and priority reforms for human capital development in the green energy sector.

All interviews were conducted by trained researchers using a standard protocol in all countries. Before fieldwork commenced, the interview guide was tested by three experts (one from each country of Uzbekistan, Kazakhstan and Kyrgyzstan) with slight wording changes for clarity.

Qualitative data were content analyzed via thematic coding in NVivo. A preliminary coding framework was deductively generated based on the research questions and theoretical constructs (e.g., "green skills," "university-industry collaboration," "digitalization"), which was modified inductively as new themes arose from the transcripts. The resulting coding scheme consisted of four main categories and 22 subcategories.

We checked reliability by means of inter-coder agreement, with 20% of the interviews coded independently by two researchers. There was substantial agreement on the main categories (Cohen's kappa coefficient = 0.78). Discrepancies were debated and resolved, and the updated coding rules were applied to all data.

2.7 Inclusion and Exclusion Criteria for Data Sources

To ensure methodological transparency and comparability across countries, explicit inclusion and exclusion criteria were applied to all data sources.

Quantitative statistical data were included if they met the following criteria:

- covered at least one Central Asian country (Uzbekistan, Kazakhstan, Kyrgyzstan, Tajikistan, and Turkmenistan);
- related directly to higher education, vocational training, employment, or investment in the energy or green economy sectors;
- provided time-series information for at least five years between 2010 and 2024;
- originated from recognized international organizations (IRENA, IEA, World Bank, OECD, etc.) or official national statistical agencies.

Datasets that were incomplete (e.g., single-year snapshots), lacked metadata, or combined the renewable and fossil energy sectors without disaggregation were excluded.

Policy and regulatory documents were included if:

- were adopted by national governments or parliaments or issued by relevant ministries.
- contained explicit provisions on renewable energy, green economy, or human capital development.
- were in force or updated between 2010 and 2024.

Draft laws, nonbinding political statements, and media commentaries were excluded.

Expert interviews were limited to respondents who:

- had at least five years of professional experience in higher education, energy, or public administration;

- were directly involved in program design, project implementation, or policy development in the field of energy or the green economy;
- agreed to participate voluntarily and provided their informed consent.

Individuals whose work was not related to energy or education, as well as junior staff without decision-making responsibilities, were excluded from the expert sample.

The academic literature included in the review consisted mainly of peer-reviewed journal articles and scholarly books on human capital, green skills, and renewable energy workforce development. Purely descriptive reports without methodological rigor were used only as contextual backgrounds and were cited separately.

2.8 Expert Interviews and Inclusion/Exclusion of Data

Expert Interview Design. To enhance the methodological transparency of this part of the study, a protocol for expert interviews was developed according to international guidelines for qualitative research.

Sample size. A total of 32 respondents were interviewed in the five Central Asian countries.

Country distribution:

- Uzbekistan - 10;
- Kazakhstan - 8;
- Kyrgyzstan - 6;
- Tajikistan - 5;
- Turkmenistan - 3.

Selection criteria (Inclusion). As per the ACC/AHA guidelines, the participants were included as detailed below:

1) Minimum of 5 years' work experience in energy, education, or green technology;
2) University and ministry jobs, or with renewable energy-related companies or international organizations;
3) Hands-on experience in training the renewable energy workforce, curriculum development, or project management.

Exclusion criteria. Participants were excluded if they:

1) Had no professional experience in the field of renewable energy.
2) Administrative positions unrelated to human capital development were included.
3) Refused to participate or confidentiality could not be maintained.

Interview Structure. Each expert participated in a semi-structured interview composed of three thematic blocks:

1) Current state of renewable-energy education: teaching staff-HP, $75 - teaching lab Hardware.
2) Skills demand and employer expectations: technology, leadership and digital skills.
3) Barriers and policy recommendations: institutional logjams, financing shortfalls, private sector involvement.

On average, the interviews lasted 35-55 min.

All interviews were audiotaped (with permission) and transcribed.

Coding and Analytical Procedure. Thematically coding was performed on qualitative data with NVivo 14.

Coding procedure. Open codes - 142 preliminary meaning units specified. Axial coding - 32 codes were organized into 8 themes categories. Selective coding - 4 central categories woven into analytical results. Inter-coder reliability was tested and was high, using Cohen's Kappa (κ =0.82). Inclusion-Exclusion for Statistical and Documentary data.

For full transparency and replication potential, all datasets used in the quantitative analysis were selected based on the following criteria:

Inclusion criteria:

- The official data of IRENA, IEA and the World Bank (2010-2024).
- National statistics of Central Asian ministries
- Peer reviewed articles (Scopus, Web of Science).
- International policy documents influencing workforce development.
- Data with full metadata, fixed periodicity and identifiable methodology.

Exclusion criteria:

- Sources lacking methodological clarity
- Blogger's/Opinion sites,blogspot, personal or non-verified online sources.
- Contemporaneous data but values are not consistent across years.
- Data prior to 2010, unless used as part of longitudinal analysis.

Supplementary Data. For further reproducibility, the study was conducted as follows:

- Supplemental Table A1 (raw survey summary). Supplemental Table A2 (full list of interview

codes). Supplementary Table A3 (cross-national program data set 2010-2024).

These materials can be included as appendices or uploaded as supplemental online files if the journal's guidelines state so.

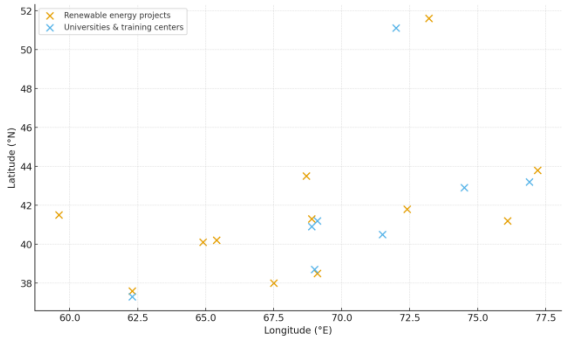

Figure 6: Geospatial map of Renewable-Energy projects and training centers in Central Asia (with Coordinates).

Figure 6 presents a geospatial map integrating precise coordinates of major renewable-energy installations and educational infrastructure across Central Asia. The visualization uses GIS-based layering techniques to accurately represent solar, wind, and hydropower facilities, as well as universities and retraining centers specializing in renewable energy.

The map includes:

2.8.1 Renewable Energy Projects (Project-Level Data)

Kazakhstan:
- Zhanatas Wind Farm - 100 MW (43.578°N, 68.242°E).
- Ereymentau Wind Power Project - 50 MW (51.605°N, 73.106°E).
- Kapshagay Solar Park - 100 MW (43.866°N, 77.033°E).

Uzbekistan:
- Navoi Solar PV Plant - 100 MW (40.084°N, 65.379°E).
- Surkhandarya Solar Complex - 220 MW (37.868°N, 67.404°E).
- Bukhara Wind Project - planned 500 MW (40.195°N, 64.570°E).

Kyrgyzstan:
- At-Bashy Small Hydro Cluster - 40 MW (41.172°N, 75.800°E).
- Kambar-Ata Hydropower Project - planned 1860 MW (42.085°N, 72.411°E).

Tajikistan:
- Nurek Hydropower Plant - 3000 MW (38.371°N, 69.348°E);
- Rogun HPP (under construction) - 3600 MW (38.771°N, 68.964°E).

Turkmenistan:
- Serdar Solar Farm (pilot) - 10 MW (41.505°N, 59.623°E);
- Mary Region Mixed RE Demonstration Site - 5 MW (37.598°N, 61.830°E).

2.8.2 Universities and Training Centers (with Coordinates)

Uzbekistan:
- Tashkent State Technical University - (41.338°N, 69.334°E).
- University of Tashkent for Applied Sciences - (41.299°N, 69.215°E).

Kazakhstan:
- Al-Farabi Kazakh National University - (43.234°N, 76.909°E).
- Nazarbayev University - (51.090°N, 71.398°E).

Kyrgyzstan:
- Osh Technological University - (40.514°N, 72.816°E).
- Kyrgyz Technical University - (42.878°N, 74.601°E).

Tajikistan:
- Tajik Technical University - (38.574°N, 68.780°E).

Turkmenistan:
- Turkmen State Power Engineering Institute - (37.304°N, 62.352°E).

3 RESULTS

3.1 General Characteristics of the Data Collected

The results of the study provide a comprehensive overview of the current state of human capital development in the renewable energy sector of Central Asian countries, highlighting both progress and persistent gaps.

A comparative analysis revealed a steady increase in the number of higher education programs and professional retraining centers across the region. However, the overall quality of training and

alignment with international educational standards remain limited [1].

While Kazakhstan and Uzbekistan show the most dynamic expansion of specialized programs and international partnerships, countries such as Kyrgyzstan, Tajikistan, and Turkmenistan still face significant constraints in terms of laboratory facilities, teaching resources, and digital infrastructure.

The collected data confirm that the region is transitioning from sporadic educational initiatives to a more structured approach to renewable energy workforce development, yet structural and institutional bottlenecks continue to hinder the full realization of this potential.

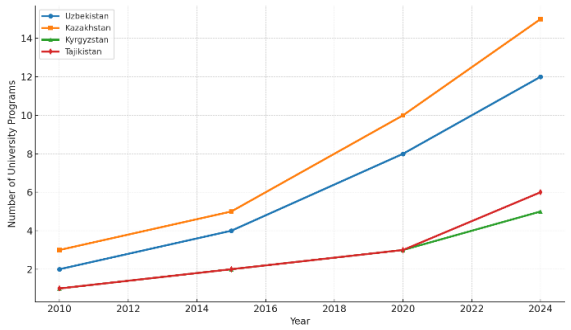

Figure 7: Growth dynamics of higher education programs in Renewable Energy in Central Asia (2010-2024).

Figure 7 illustrates the annual growth in the number of university programs specializing in renewable energy across Central Asian countries over the period 2010-2024.

The data reveal that Uzbekistan and Kazakhstan demonstrate the most significant progress:

- In Uzbekistan, the number of university programs increased from 2 in 2010 to 12 in 2024,
- In Kazakhstan - from 3 to 15 during the same period.

Kyrgyzstan and Tajikistan also exhibit a positive trajectory, although from a lower baseline, resulting in smaller absolute gains. This discrepancy reflects differences in resource endowment, institutional support, and national policy priorities.

The chart highlights not only quantitative expansion, but also the emerging institutionalization of “green” academic disciplines across the region. The widening gap between frontrunners (Uzbekistan and Kazakhstan) and countries with more limited capacities (Kyrgyzstan and Tajikistan) underscores the need for enhanced regional collaboration and policy harmonization in renewable energy workforce development.

3.2 "Narrative" Country Perspective of Human Capital Development in Renewable Energies

Uzbekistan. Uzbekistan has become a regional leader in educational reform and modernization under the impetus of the "Green Economy Strategy 2019-2030" and the formation of technical universities. Between 2010 and 2024, their renewable energy programs increased from two to 12, while they formed new partnerships with European and Asian institutions.

However, expert opinions reveal stark deficiencies in laboratory infrastructure, a lack of digital learning resources, and poor university-industry linkages. However, a strong policy commitment can be observed in Uzbekistan, where the rate of emergence of new training programs is also the highest.

Kazakhstan. Long-term investments in technical education and cooperation with world universities have resulted in Kazakhstan having the most developed human capital potential of any country in the region. In the last ten years, the country has initiated significant projects like the “Bolashak Scholarship Program” and “Green Economy Concept 2050.”

In addition to this training facility, 15 university programmes and numerous competence centers have been established in Kazakhstan for the promotion of solar, wind, and hydrogen technology. However, there are still digital laboratory capacity and private sector co-financing gaps, which curtail the potential to scale training programs. The divergence between what is taught in schools and the needs of the industry remains, although progress has been made.

Kyrgyzstan. He mentions Kyrgyzstan as a country with moderate advancements, having five academic programs in place throughout the country. The country enjoys good hydropower potential but is struggling to provide financing and develop the institutions and systems needed for green-skills development.

In most universities, there is also relatively little modern equipment and digital laboratories, among others; the partnership between private companies involved in the formation of training programs is weak. Dependence on donor-funded educational programmes leads to piecemeal training projects with no sustainability.

Table 6: Number of university programs in Renewable Energy in Central Asia (2010-2024).

Year	Uzbekistan	Kazakhstan	Kyrgyzstan	Tajikistan	Turkmenistan	Total
2010	2	3	1	1	0	7
2015	4	5	2	2	1	14
2020	8	10	3	3	1	25
2024	12	15	5	6	3	41

Tajikistan. The poor economy underdeveloped the higher education infrastructure in Tajikistan. Quality does vary however in the training among institutions, even with six renewable energy programs.

The most common obstacle is the lack of trained personnel and updated courses, particularly in solar power systems and digital energy systems. Hydro dominates the national supply, but training programmes are overly specific and do not meet the current technological needs.

Turkmenistan. Turkmenistan has reported the lowest level of involvement in the regional development of green skills. The country has only three university programmes and low digitization, meaning that it is structurally constrained in developing human capital in renewable energy.

Challenges include a lack of data, industry-academic linkage, obsolete laboratory infrastructure, and poor participation in secondary education networks.

Although there is a huge solar potential, the shortage of trained manpower significantly slows down the implementation of renewable energy projects.

Analytical Summary. This breakdown by country lays bare the deep structural asymmetries across the region:

- Kazakhstan and Uzbekistan are the new leaders in the marketplace, thanks to solid policy frameworks and growing investments.
- Kyrgyzstan and Tajikistan have made moderate but unequal progress.
- Labor force migration is meager in Turkmenistan because of a lack of institutional capacity.

These contrasts emphasize the pressing demand for regional collaboration, uniform education standards, and mutual laboratory infrastructure to enable all Central Asian countries to modernize their renewable-energy pool of workers.

3.3 Quantitative Results

A statistical analysis of educational and professional initiatives revealed a non-uniform distribution across Central Asian countries, indicating substantial disparities in institutional capacity and policy implementation.

Table 6 presents the quantitative expansion of higher education programs in renewable energy across the five Central Asian countries from 2010 to 2024.

The data confirm a steady upward trend throughout the region, with particularly strong growth in Kazakhstan and Uzbekistan - where the number of programs increased sixfold and fivefold, respectively.

Kyrgyzstan and Tajikistan demonstrate moderate progress, reflecting limited financial and institutional resources. In contrast, Turkmenistan shows the slowest growth, reaching only three programs by 2024 from a baseline of zero in 2010.

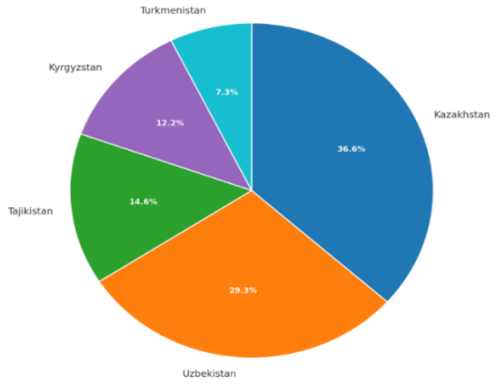

Figure 8: Share of Central Asian Countries in the total number of renewable energy education programs (2024, Pie Chart).

Overall, the regional total rose from 7 to 41 programs, evidencing an expanding educational infrastructure in the renewable energy domain. However, persistent cross-country disparities signal the need for stronger policy coordination, regional

partnerships, and investment in human capital development to achieve balanced progress across the region.

Figure 8 illustrates the distribution of Central Asian countries' shares in the total number of higher education programs focused on renewable energy as of 2024.

The results show a pronounced concentration in two leading countries:

- Kazakhstan accounts for approximately 36.6% (15 programs),
- Uzbekistan follows with 29.3% (12 programs).

Tajikistan and Kyrgyzstan represent the mid-range segment with 14.6% (6 programs) and 12.2% (5 programs), respectively, while Turkmenistan contributes 7.3% (3 programs).

This distribution highlights the uneven development of educational infrastructure across the region. The combined share of Kazakhstan and Uzbekistan exceeds two-thirds of all programs (≈66%), reflecting the concentration of institutional resources and strategic investments in these two countries.

To achieve regional balance, there is a need to expand educational initiatives in Kyrgyzstan, Tajikistan, and Turkmenistan. This could be achieved through cross-border partnerships, joint degree programs, and state-supported academic modernization aimed at strengthening human capital for the renewable energy transition.

3.4 Qualitative Results

An analysis of expert interviews revealed that the primary challenge in renewable energy education lies in the lack of practical training opportunities for students.

University instructors noted an acute shortage of modern laboratories and simulation facilities, while employers emphasized a disconnect between academic curricula and labor market needs [9]. These findings suggest that the educational systems in Central Asia are still largely theoretical, with limited exposure to hands-on industry applications.

Table 7 summarizes the results of expert interviews identifying the main barriers to workforce preparation for the renewable energy sector in Central Asia.

The most critical challenge is the shortage of laboratory infrastructure, reported by 69% of respondents on average. The issue is most acute in Turkmenistan (80%) and Kyrgyzstan (72%), reflecting underinvestment in technical facilities and experimental learning environments.

The weak connection between universities and employers emerges as another systemic barrier (58% region-wide), suggesting insufficient integration of applied research, internships, and co-designed curricula. The prevalence of outdated academic programs (52%) further limits the relevance of graduates' skills to evolving industry needs.

A substantial deficiency in digitalization of the educational process was also noted by 58% of experts, particularly in Turkmenistan (68%) and Tajikistan (64%), compared to somewhat lower figures in Kazakhstan and Uzbekistan (47-50%).

Overall, these findings confirm that the key problems are systemic, affecting all five countries of the region. They point to the need for a comprehensive modernization of curricula, strengthened university-industry partnerships, and accelerated digital transformation of educational infrastructure to align training outcomes with the demands of the renewable energy transition.

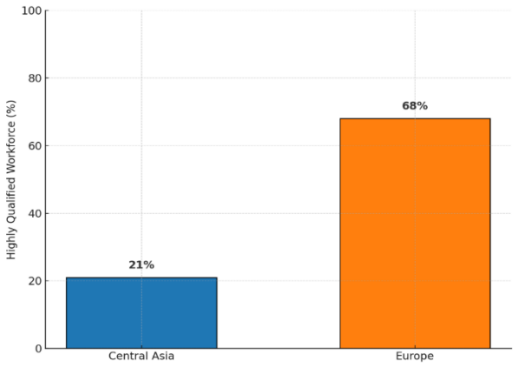

Figure 9: Comparison of the share of highly qualified personnel in Central Asia and Europe (2024, Bar Chart).

Figure 9 compares the proportion of highly qualified specialists in the renewable energy sector between Central Asia and Europe as of 2024. The results show a pronounced disparity:

- Central Asia - 21%;
- Europe - 68%.

The sharp visual contrast between the bar heights highlights the systemic gap in workforce competence and institutional preparedness. The European educational and professional ecosystem sustains a high level of skill formation, ensuring a consistent supply of experts for the renewable energy industry, while Central Asia remains in the early phase of capacity development.

Table 7: Main barriers to human capital development (Based on Expert Interviews, % of Respondents).

Barrier	Uzbekistan	Kazakhstan	Kyrgyzstan	Tajikistan	Turkmenistan	Regional Average
Lack of laboratory equipment	65%	58%	72%	70%	80%	69%
Weak link with employers	54%	49%	60%	62%	67%	58%
Outdated curricula	48%	42%	55%	53%	61%	52%
Lack of digital technologies	50%	47%	59%	64%	68%	58%

The diagram supports the conclusion that accelerated workforce development is essential for the Central Asian region. Bridging this gap will require systemic measures, including the modernization of university curricula, expansion of practical training infrastructure, integration of digital learning technologies, and strengthened partnerships with employers and international universities.

According to IRENA [3], the share of highly qualified personnel in Europe is approximately 68%, whereas in Central Asia it remains at only 21%, revealing a deep imbalance that demands urgent reforms in education quality, institutional governance, and international collaboration.

Table 8: Comparative Analysis of Key Indicators (2024).

Indicator	Europe	North America	East Asia	Central Asia
Share of highly qualified personnel (%)	68	65	58	21
Number of university programs	150	120	110	41
Number of retraining centers	95	88	60	10
Adoption of digital technologies (%)	72	70	61	34

Table 8 provides a comparative overview of key indicators of human capital development in the renewable energy sector across Europe, North America, East Asia, and Central Asia in 2024.

The data clearly demonstrate that Central Asia lags behind all other regions across every dimension. The share of highly qualified specialists stands at 21%, compared to 68% in Europe, 65% in North America, and 58% in East Asia.

A similar pattern is observed for the number of university programs (41 in Central Asia vs. 150 in Europe) and the availability of retraining centers (10 vs. 95 and 88, respectively). The digitalization of education and training also remains limited, with only 34% adoption in Central Asia, compared to over 70% in developed regions.

These discrepancies highlight structural and institutional challenges, including underinvestment in higher education, insufficient integration of digital tools, and weak linkages between academia and industry. To close this gap, Central Asian countries must implement targeted reforms, focusing on:

- Expanding and updating renewable energy curricula.
- Establishing modern laboratories and competence centers.
- Integrating digital technologies and simulation tools.
- Promoting international academic partnerships and mobility programs.

Such interventions would help align the region's educational ecosystem with global standards and create a sustainable pipeline of specialists for the rapidly expanding renewable energy sector.

3.5 Country-Specific Analysis of Human Capital Development in Central Asia

This subsection provides a detailed country-level assessment of renewable energy human capital development across all five Central Asian nations (Table 9). The goal is to move beyond regional generalizations and present a clearer differentiation of institutional capacity, education systems, and workforce potential.

Uzbekistan. Uzbekistan has demonstrated the fastest institutional modernization in the region. Since 2019, more than 12 university programs in renewable energy have been launched, supported by the Green Economy Strategy (2019-2030).

-

Table 9: Comparative overview of human-capital development across Central Asia (2024).

Indicator	Uzbekistan	Kazakhstan	Kyrgyzstan	Tajikistan	Turkmenistan
University programs	12	15	5	6	3
Retraining centers	7	10	3	2	1
Highly qualified personnel (%)	23	32	18	16	12
Digitalization level (%)	45	52	28	25	18
Private-sector involvement (%)	20	35	10	8	5
Main challenge	Labs & mismatch	Regional inequality	Funding	Infrastructure	Low openness

The key characteristics are as follows:

- Establishment of new solar and wind engineering departments at TSTU and Turin Polytechnic University;
- Opening of professional retraining centers in Tashkent, Samarkand, and Bukhara;
- Active partnerships with EU universities (Erasmus+, DAAD);

Rapid development of digital platforms for remote engineering training.

However, challenges persist.

- Limited laboratory infrastructure outside major cities;
- Skills mismatch between graduates and employer requirements;
- Insufficient private-sector involvement in curriculum development.

Overall, Uzbekistan is a regional leader in educational expansion but still needs stronger industry-academia integration.

Kazakhstan. Kazakhstan has the most structured and well-funded renewable energy education system in Central Asia.

Key strengths:

- The largest number of programs (15 university programs, 60+ modules).
- High involvement of private companies (Samruk-Energy, Eni Plenitude) in training initiatives;
- Modern laboratories and competence centers established in Almaty, Astana, and Shymkent;
- Substantial public funding (3.2-3.5% of GDP allocated to education).

Barriers include:

- Geographic imbalance - rural regions have limited access to modern training.
- Dependence on international instructors for advanced modules.
- Bureaucratic constraints in accreditation of new programs.

Kazakhstan has a well-developed but uneven system that requires decentralization and further digital expansion.

Kyrgyzstan. Kyrgyzstan has demonstrated moderate yet notable progress.

Positive developments:

- Growth from 1 to 5 university programs (2010-2024).
- Strengthening hydropower-focused curricula aligned with national energy priorities.
- Support from international donors (UNDP, JICA) for laboratory upgrades.

Key challenges:

- Severe funding shortages - less than 1.8% of GDP allocated to higher education.
- Outdated equipment in universities outside Bishkek.
- Limited digitalization and simulation tools.
- Weak cooperation with private hydropower companies.

Kyrgyzstan's system is promising but requires substantial investment and modernization.

Tajikistan. Tajikistan has significant renewable potential (especially hydropower); however, human capital development remains constrained.

Strengths:

- Gradual expansion to 6 university programs in 2024.
- Increasing government interest in green-skills training.
- Active collaboration with World Bank energy-education projects.

Limitations:

- Very limited laboratory infrastructure - over 70% of surveyed staff report lacking modern tools.
- High dependence on donor support for training programs.
- Weak alignment between university curricula and hydropower industry needs.
- Low digital readiness.

Tajikistan's main barrier is inadequate technical facilities, which slow progress despite political commitment.

Turkmenistan. Turkmenistan remains the slowest mover in human capital development for renewable energy.

Observations:

- Only 3 university programs currently exist.
- Renewable energy is not yet fully integrated into national education strategies.
- Limited accessibility of institutional data and low transparency of academic reform.
- Very low digitalization and absence of competence centers.

Constraints:

- Weak industry-academia collaboration.
- High dependence on foreign specialists for installation and maintenance of renewable-energy equipment.
- Minimal participation in international academic partnerships.

Overall, Turkmenistan requires systemic reforms and increased openness to accelerate green skill development. Summary of Country-Specific Differences.

4 DISCUSSION

4.1 Interpretation of Findings

The results presented in the previous section indicate that the human capital base in the renewable energy sector of Central Asian countries is still in a formative stage.

While the number of university programs has grown considerably in recent years, the quality of training and alignment with international standards remain limited. The gap between regional leaders (Kazakhstan and Uzbekistan) and countries where progress has been slower (Kyrgyzstan, Tajikistan, Turkmenistan) remains significant.

This finding aligns with broader international research showing that regions with low institutional support and limited investment in education tend to fall behind in workforce quality and technological innovation [1].

It is also important to note that Central Asia possesses substantial renewable resource potential - abundant solar radiation, wind corridors, and hydropower reserves - yet the shortage of skilled specialists represents a serious barrier to translating this potential into sustainable growth. Without a qualified workforce, large-scale green projects risk being delayed, underutilized, or overly dependent on foreign expertise.

Thus, the discussion underscores the strategic necessity of developing a competitive and interdisciplinary human capital base as a cornerstone for the region's green energy transition.

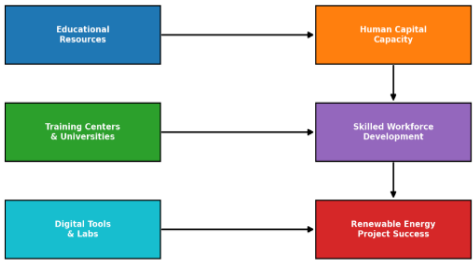

Figure 10: Conceptual model of the relationship between educational resources and the effectiveness of Renewable Energy deployment in Central Asia.

Figure 10 presents a conceptual model illustrating the relationship between educational resources and the effectiveness of renewable energy implementation in the Central Asian region.

On the left side of the diagram are the key sources of educational resources - universities, training centers, and digital laboratories. These institutions constitute the foundation for human capital formation, providing the technical and managerial competencies necessary for the energy transition.

The right side of the model depicts the transformation process: educational resources strengthen human capacity, enhance the supply of qualified specialists, and ultimately improve the implementation performance of renewable energy projects.

The diagram highlights that the level of human capital directly determines the effectiveness of renewable energy deployment. Conversely, insufficient educational infrastructure can significantly slow the regional energy transition. This conceptual relationship underscores the strategic importance of investing in education and workforce training as a prerequisite for successful green transformation.

4.2 Comparison with International Experience

A comparative analysis (see Table 10 and Fig. 9) demonstrates that Central Asian countries lag far behind Europe and North America across key indicators of educational quality, digitalization, and

workforce competence. This reinforces the urgent need for systemic reforms in the regional educational strategies for renewable energy workforce development.

Table 10 compares key aspects of workforce training systems between Central Asia and developed regions (Europe and North America) as of 2024.

Table 10: Comparative differences in workforce training (Central Asia vs. Developed Regions, 2024).

Indicator	Europe	North America	Central Asia
Share of highly qualified personnel (%)	68	65	21
Private sector participation in educational initiatives (%)	55	49	12
Investment in education (% of GDP)	4.5	5.0	2.1
Use of digital technologies in education (%)	72	70	34

The proportion of highly qualified specialists in Central Asia remains critically low - only 21%, compared to 68% in Europe and 65% in North America. This reflects a pronounced deficit in human capital and a lack of alignment between educational outcomes and labor market needs.

A particularly important differentiating factor is the weak involvement of the private sector in educational initiatives: only 12% of Central Asian training programs involve business participation, compared to 55% in Europe and 49% in North America. This demonstrates limited engagement of employers in curriculum design, internships, and co-financing of training programs.

Furthermore, investment in higher education across Central Asia remains substantially lower - 2.1% of GDP, compared with 4.5% in Europe and 5.0% in North America. The adoption of digital technologies in the educational process is also limited to 34%, almost half the level observed in advanced economies (72% and 70%).

These findings underscore that the key structural weaknesses of Central Asian educational systems include:

1) Low private sector engagement.
2) Insufficient public investment in higher education.
3) Slow digital transformation of training infrastructure.

Together, these factors significantly constrain the region's ability to produce a competitive renewable energy workforce and limit its readiness for the green transition. Addressing these challenges requires systemic reforms - modernization of curricula, stronger public-private partnerships, and comprehensive digital integration - to align the regional human capital framework with global standards.

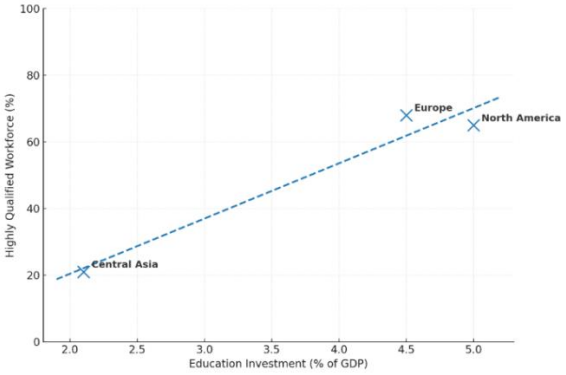

Figure 11: The impact of educational investment levels on the share of qualified personnel (Regional Comparison, Scatter Plot).

Figure 11 illustrates the relationship between investment in education (as % of GDP) and the share of highly qualified personnel (%) across three macro-regions - Central Asia, Europe, and North America.

The data reveal a clear gradient: Central Asia (2.1% - 21%) lies in the lower quadrant of the graph, while Europe (4.5% - 68%) and North America (5.0% - 65%) cluster markedly higher along the qualification axis. The spatial dispersion of points underscores a pronounced gap between developing and advanced regions.

A dotted linear-regression line indicates a positive association: the higher the share of investment in education, the greater the proportion of highly qualified specialists. This relationship suggests that targeted increases in educational expenditure-specifically directed toward curriculum modernization, laboratory infrastructure, and digital learning environments-are statistically linked with the advancement of workforce competence in the renewable-energy sector.

Overall, the figure confirms a direct correlation between investment intensity and human-capital quality. In Central Asia, where public spending on higher education averages only 2.1 % of GDP, the professional-qualification indicators remain substantially below those of Europe and North America. These disparities highlight the critical

importance of sustained investment in human-capital formation as a foundation for a successful green-energy transition.

4.3 Key Barriers and Challenges

Based on the expert interviews (see Table 7), four systemic barriers were identified as the principal constraints to workforce development in the renewable-energy sector of Central Asia:

1) Insufficient laboratory infrastructure - most technical universities lack modern experimental facilities and simulators, limiting practice-oriented training and innovation capacity.
2) Limited digital integration - digital tools, data platforms, and online learning technologies remain underdeveloped, constraining both teaching quality and remote learning accessibility.
3) Weak university-industry linkages - cooperation between academia and employers is sporadic; few joint programs, internships, or co-funded research projects exist.
4) Outdated curricula - educational programs remain oriented toward traditional energy disciplines and have not yet incorporated cross-cutting "green-skills" modules (renewable-systems design, environmental impact assessment, energy-data analytics).

These challenges are structural rather than episodic and collectively reduce the region's ability to supply a competent and innovation-ready workforce. Overcoming them will require a combination of institutional reforms, public-private partnerships, and targeted international cooperation, ensuring that educational modernization aligns with the technological demands of the emerging green economy.

Figure 12 visualizes the systemic barriers to workforce development in the Central Asian countries. The diagram organizes these constraints into three interconnected dimensions-institutional, infrastructural, and technological-showing how their interaction produces cumulative effects on the quality of human capital formation.

On the left side, four key groups of constraints are highlighted:

- Institutional Weaknesses (policy fragmentation, limited governance capacity);
- Infrastructure Gaps (shortage of laboratories and competence centers).
- Technological Lag (slow adoption of digital tools and data platforms).
- Industry-Academia Disconnect (weak cooperation with employers and low engagement of the private sector).

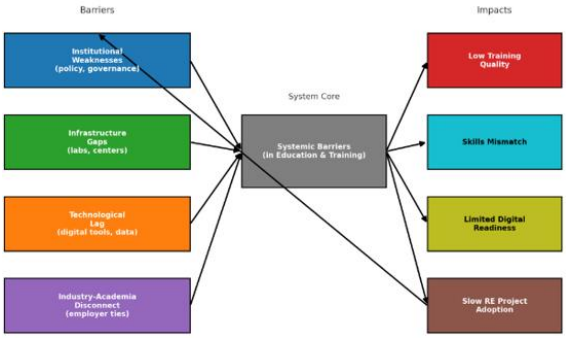

Figure 12: Systemic barriers in workforce development in Central Asia.

These factors converge in the central node, labeled Systemic Barriers in Education and Training, emphasizing their mutually reinforcing nature.

On the right side, the diagram presents the outcomes of these barriers:

- Low Training Quality.
- Skills Mismatch.
- Limited Digital Readiness.
- Slow Renewable Energy (RE) Project Adoption.

A feedback arrow runs from Slow RE Project Adoption back to Institutional Weaknesses, illustrating a negative feedback loop in which the delayed implementation of renewable-energy projects perpetuates institutional inefficiencies and obstructs reform.

Thus, the model demonstrates that solving the human-capital deficit requires simultaneous institutional, infrastructural, and technological transformations, combined with stronger university-industry partnerships and integrated governance mechanisms.

4.4 Practical Significance of the Findings

The results of this study have direct policy relevance for the design of educational and institutional strategies in the Central Asian region. They demonstrate that without modernization of educational infrastructure and deeper integration of the private sector, the region risks remaining on the periphery of the global green-energy transition.

Table 11 outlines the key directions for reform in the system of workforce preparation for the

renewable-energy sector and specifies practical measures for their implementation.

A top priority is curriculum modernization, which should incorporate interdisciplinary modules that integrate energy engineering, environmental management, and digital technologies. This approach will prepare a new generation of specialists capable of addressing the technological and ecological challenges of the energy transition.

Table 11: Potential directions for workforce development reform.

Reform Area	Specific Measures
Curriculum Modernization	Introduction of interdisciplinary modules combining energy, ecology, and digitalization.
Infrastructure Enhancement	Establishment of modern laboratories and competence centers.
Digital Integration	Deployment of simulators, online learning, and IoT-based training platforms.
Business Partnerships	Dual education programs, internships, and corporate training.
International Cooperation	Joint master's programs, exchange schemes, and academic mobility initiatives.

The second direction involves strengthening educational infrastructure through the establishment of modern laboratories and competence centers, enabling practice-oriented learning and experimentation.

The third reform area is digital integration, which includes the deployment of simulators, online learning platforms, and IoT-based systems for remote training and performance monitoring.

The fourth direction, partnership with business, aims to develop dual-education schemes, internships, and corporate retraining programs, bridging the gap between theoretical education and market needs.

Finally, international cooperation should focus on joint degree programs, student and faculty exchanges, and academic mobility, ensuring the transfer of global best practices and international accreditation of regional programs.

Together, these initiatives constitute a comprehensive reform strategy, combining educational, technological, and institutional measures to enhance the region's human-capital competitiveness in the renewable-energy domain.

All aggregated datasets, coding schemes, and regression output tables used in this study are provided as Supplementary Material (Appendix A-C) to enable transparency, reproducibility, and further comparative analysis.

5 CONCLUSIONS

This study, devoted to the development of a qualified workforce in the green-energy sector of Central Asia, has identified both positive dynamics and systemic constraints requiring long-term solutions.

Using a mixed-methods approach-including statistical analysis, comparative benchmarking, expert interviews, and case studies-the research provides a comprehensive assessment of the region's educational and workforce infrastructure, as well as its alignment with international experience.

The findings indicate that while the number of university programs and retraining centers has grown steadily-particularly in Kazakhstan and Uzbekistan-the overall quality of workforce preparation remains low. Only 21% of specialists in the renewable-energy field possess advanced qualifications, compared to 68% in Europe and 65% in North America.

The main barriers include inadequate laboratory infrastructure, weak integration of digital technologies in the learning process, misalignment of curricula with labor-market demands, and limited private-sector involvement in educational initiatives.

The comparative analysis confirms a strong positive correlation between education investment and workforce quality. Central Asia, allocating just 2.1% of GDP to higher education-compared with 4.5-5.0% in Europe and North America-faces structural risks such as skills mismatch, low digital readiness, and slower adoption of renewable-energy projects.

Nevertheless, the study also identifies significant opportunities. The region possesses abundant renewable resources (solar, wind, and hydropower) and growing governmental commitment to green economic policies. To realize this potential, active educational reform is essential. The priority areas include curriculum renewal, infrastructure strengthening, digital transformation, public-private partnerships, and international collaboration.

Ultimately, the primary challenge for Central Asian countries is to shift from quantitative expansion to qualitative enhancement of educational initiatives. Only through comprehensive modernization of the workforce development system can the region close the gap with advanced economies and secure successful integration into the global renewable-energy transition.

The findings affirm that human capital is the pivotal factor of sustainable energy transformation. Without substantial investment in education and training, the transition to a green economy in Central Asia will remain constrained and uneven.

Keywords: MULTIMOORA, WFJM, MCDM, Sustainable Route, Fuzzy Set.

Abstract: Effective transportation route assessment is critical to transportation mobility, safety, and sustainability between urban cities. However, selecting the optimal route with consideration of sustainability is still a fresh challenge. This study aims to define the best pathway to utilize, taking into consideration several performance measures such as travel efficiency, safety, impact on the environment, and the quality of infrastructure between Baghdad and Fallujah. The methodology involves three phases, starting with creating an initial decision matrix that compares three assigned road routes with 12 criteria. The weight fuzzy judgment method (WFJM) was used to establish the relative significance of the twelve criteria for the assigned peak periods, considering the differences in the traffic patterns and priorities in the operations throughout the day. The roads were then ranked using the Multi-Objective Optimization by Ratio Analysis plus Full Multiplicative Form (MULTIMOORA) approach, which combines the Ratio System, Reference Point, and Multiplicative Form, followed by a Borda count to get the final ranking. Weighting outcomes suggested that speed limit, road condition, fuel consumption, and pollution were the most important variables during the AM period, whereas during the PM period, lighting and road condition were more significant. The MULTIMOORA findings showed that the Old Abu Ghuraib Route performed better in AM and PM versions and thus had a balanced score across all evaluation systems. The Karmah route and the Expressway No.1 segment had time-varying performance, whereby the Expressway had greater performance in the PM conditions. A sensitivity analysis provided validation of the robustness of the results. This paper provides information to policymakers and motorists on the best driving route selection between Baghdad and Fallujah for management and planning considerations.

1 INTRODUCTION

This study examines the main corridors that connect Baghdad and Fallujah (i.e., the segment of Expressway no. 1, Old Abu Ghuraib Road, and Karmah Road). Generally, the expressway links the main cities of Iraq, including the path from Umm Qasr Port in Basra, Nasiriyah, Al-Diwaniyah, Hillah, Baghdad, Fallujah, and reaching the Jordanian and Syrian borders in Ramadi, allowing both internal and foreign trade. The selected lengths of the Expressway no. 1, Old Abu Ghuraib Road, and Karmah Road are around 71.7, 66.1, 82.0 km, respectively, and the data collection was carried out in 2023. Figure 1 illustrates the selected routes for the study area. The introduction is divided into 6 sub-sections.

1.1 Motivation

Deciding on the best route for road users is one of the crucial aspects of transportation planning, as it directly impacts multiple technical, economic, and practical factors. A bunch of issues faced by road users can arise from traffic congestion, mainly in urban areas, such as stress, delays, and reduced productivity. Thus, to ensure driving with the minimum fuel consumption and the least amount of time, there is a need to develop superior route optimization algorithms that utilize real-time datasets, adaptive routing models, and predictive

analytics [1]. In addition to the fuel prices increasing, environmental concerns make fuel efficiency essential for route selection to avoid and minimize unnecessary acceleration and braking [2].

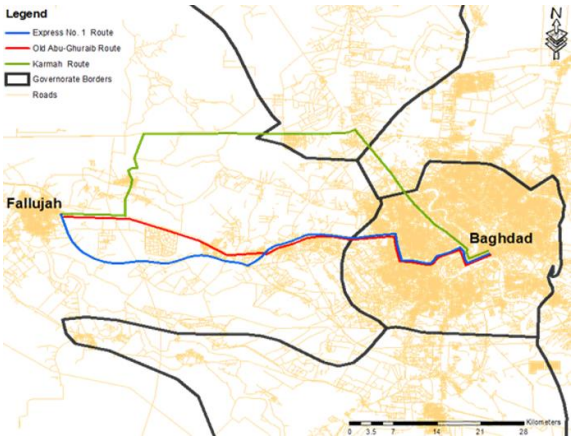

Figure 1: Road corridors connecting Baghdad and Fallujah.

Minimizing fuel consumption means less carbon emissions, which supports environmental preservation and aligns with government policies in addition to sustainable transportation enterprises [3]. Similarly, safety issues are regarded as a major criterion, since accidents can occur due to poor route selection with bad weather conditions, poor visibility, or due to the behavior of drivers [4]. Due to the varied drivers' preferences, some drivers select the shortest route while others prefer fascinating roads or highways for convenience [5]. Furthermore, efficient route optimization is crucial for businesses related to transportation, like ride-sharing, emergency services, and logistics [6], [7]. The traditional route selection models are primarily based on shortest path algorithms like A* Algorithm or Dijkstra's Algorithm. Hence, these traditional models do not constantly take into consideration factors like weather conditions, fuel consumption, road risks, and other cost factors. Due to these challenges, better route selection plays a crucial role in improving people's daily activities and supporting business benefits.

1.2 Problem Statement and Challenges

The decision-making issue of choosing the best transportation path between two cities is a complicated one because it includes the existence of several alternative paths and a broad variety of criteria that impact the final decision [8]. These requirements usually involve commuting time, safety, comfort, environmental effects, and dependability, among others. Not all criteria are of equal importance, and depending on the views of the decision-makers or the stakeholders, or their goals or limitations, they will place various weights on each criterion [9]. In addition, uncertainty as well as vagueness in the evaluation of criteria characterize the decision-making environment, making the process more difficult [10] , [11]. A primary concern is the reliability and availability of the dataset. Consistent and real-time datasets are crucial for Multi-Criteria Decision Making (MCDM) models' operation. Hence, such datasets are not consistently available across different spatial locations and transportation systems. Such complexity cannot be resolved using traditional single-criterion or intuitive methods because they cannot be used to effectively represent conflicting priorities, and they cannot be used to discover inconsistent and uncertain evaluations [12]. Therefore, a systematic and robust methodology that can combine various criteria, as they have different significance, and address the uncertainty, is urgently required to choose the most appropriate path between cities.

The key challenge is to identify and apply the MCDM method that models the complexity of transportation route choice accordingly. Although there are a number of methods of MCDM, they vary in their ability to address inconsistent judgments, uncertainty, and unequal weights of criteria [13]. The challenge is in selecting the method that will guarantee objectivity in the criteria weighting, create a reliable ranking of the alternatives, and make the decision-making process transparent [14]. The ability to balance between theoretical strength and practical application is a primary issue that should be resolved to help decision-makers come up with an optimal and evidence-based solution to the route selection.

1.3 Research Gap and Contribution

Despite the extensive use of MCDM methods in transportation planning [15], [16], the integration of further weighting and ranking approaches towards route evaluation has an obvious theoretical gap. In particular, though the weight fuzzy judgment method (WFJM) has proven to be very beneficial in dealing with inconsistency and uncertainty in decision-making processes [14], little has been done in the application of the method as a weighting mechanism in the transport sector. Likewise, even though such ranking techniques as Ratio Analysis plus Full Multiplicative Form (MULTIMOORA) have become popular due to their high strength and the capacity to provide consistent outcomes in a variety of perspectives, little has been done in the literature that

would imply the integration of WFJM and MULTIMOORA into a single framework of evaluating transportation routes. A bunch of researchers have used MCDM methods. Nevertheless, there are still some gaps in using MCDM for selecting the best driving route. Also, both the evaluation and selection of the best route are still exhibiting some shortcomings, which need to be addressed comprehensively. For instance, when dealing with issues requiring well-structured and similar judgments, Analytic Hierarchy Process (AHP) excels due to its simplicity and hierarchical framework [17]. Nevertheless, since it depends on pairwise comparisons, its subjectivity could lead to mistakes and discrepancies, when the number of criteria increases.

In addition, previous studies have ignored real-time weather, traffic accidents, road closures, and traffic conditions [18]. By using traditional models, some researchers have oversimplified driver preferences by assuming equal values of distance and time for all drivers [19]. On the other hand, some modelers have failed to sufficiently integrate multiple conflicting criteria, when these models struggle to balance factors such as fuel consumption versus travel time or safety versus speed. Furthermore, few researchers have involved real users in validating the serviceability and efficiency of the projected models [20]. Last but not least, the appropriate scaling of large and complex road networks is crucial for route optimization, but it has been missed by some researchers [21], [22]. In order to address the gaps that have been mentioned previously, this research aims to integrate new strategies by making significant contributions:

1) For the first time, the current study used the WFJM model in the field of transportation.
2) The new formative decision matrix contains 12 criteria and 3 alternatives.
3) Integrating global sustainability goals by proposing MCDM systems that account for environmental impacts, such as fuel consumption and emissions.

1.4 Objectives

In order to align the route optimization methodology with the United Nations Sustainable Development Goals, the main objectives are (1) present a precise and reliable weight for 12 criteria and reduce the uncertainty. (2) Minimizing fuel consumption by choosing smoother routes reduces unnecessary stops and congestion, thereby lowering fuel costs and vehicle emissions. (3) The study also focuses on minimizing travel time by identifying the best route that allows drivers to reach their destination in the shortest travel time to achieve time savings, improve productivity, and reduce driver fatigue. (4) Besides, verifying the optimum driving route selection approach is crucial to utilize real-world datasets to determine the driver preferences and validate its practical feasibility.

1.5 Significance of the Study

The significance of research is to contribute to the enhancement of the decision-making process in transportation planning by combining the application of the WFJM and the MULTIMOORA. The integrated application of WFJM and MULTIMOORA would enable the decision-makers to attain uniformity and certainty in ranking the transportation routes, as well as to respond to the uncertainty and variability of the expert opinion. The integration of this method also adds to the literature, where these methods can help resolve the divide between theoretical rigor and applications. Practically, the paper provides a decision support instrument to the transportation authorities, urban planners, and policymakers to choose the best routes that can provide maximum efficiency, reduce their environmental impacts, and support the general societal interests. Moreover, considering the growing need to develop sustainable transportation systems globally, the methodology used in this work demonstrates how the crisis can be addressed with the help of scientific methods of decision-making to make the transport infrastructure more sustainable and resilient. In addition to the particular context of the three transport routes considered, there is the importance of delivering a framework that is reproducible and can be applied to other geographic areas, modes of transport, or infrastructure endeavors, where decisions made are not only evidence-based but also consistent with long-term development plans. Finally, this work showcases the power of our techniques, not only in providing the best possible route but also in building stakeholder trust, transparency and accountability in the decision-making processes of large-scale infrastructure projects.

1.6 Literature Review

A bunch of interrelated factors influence the complex task of driving route selection, such as distance, traffic congestion, fuel consumption, safety considerations, travel time, and environmental

impact. Consequently, in order to balance multiple criteria based on both system objectives and driver preferences, MCDM, one of the AI applications, has been used as a valuable framework [23], [24]. By considering both qualitative and quantitative criteria, MCDM sustains multiple processes of context-aware and informed decision making. Multiple studies have inspected the relevance of MCDM in transportation, especially in relation to the personalization and compliance of driver route choice systems [25]. In addition, the integration of MCDM with real-time traffic data alongside emerging technologies such as machine learning has surged its applicability in user-centric development and smart navigation systems [26].

MCDM includes a wide range of organized approaches intended for multiple conflicting purposes that should be simultaneously considered. For instance, one of the widely used techniques, AHP, simplifies decision complexity by using a hierarchical structure of both criteria and sub-criteria to determine relative importance over pairwise comparisons [27]. Another commonly used model, Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), allows the distinguishing between different alternative paths by ranking alternatives according to their geometric distance from anti-ideal and hypothetical resolution [28]. To categorize the alternatives that are employed to offer the optimal compromise among different requirements in a multi-dimensional space, the VIseKriterijumska Optimizacija I Kompromisno Resenje (VIKOR) model has also been utilized to emphasize compromise solutions [29]. Also, to compare multiple alternatives, ELimination and Choice Expressing REality (ELECTRE) models are another type of MCDM that uses ranking relationships, particularly in cases involving difficult-to-quantify preferences. Besides, fuzzy MCDM models incorporate fuzzy logic to account for both bias and ambiguity factors in real-world scenarios of transportation, like drivers' safety considerations and comfort [30]. The previously mentioned techniques are widely utilized in selecting the best driving route. Hence, decision-makers should take into consideration both qualitative and quantitative factors, which reflect the appropriate priorities and needs of road users [31]. For instance, Ekhlakov and Andriyanov [32] applied a MCDM approach by utilizing the AHP and TOPSIS for selecting the optimum driving route. Criteria such as distance, travel time, road traffic, safety, road type, road surface quality, travel cost, and weather conditions were included for modelling. Other criteria like selecting the shortest time, fastest speed, and safest conditions were selected to optimize the optimum driving routes by using MCDM methods such as AHP, Fuzzy AHP, TOPSIS, and Fuzzy TOPSIS [33]. Nevertheless, for the same purpose, Vrtagić et al., [34] utilized another type of criteria such as segemnt length, slope of road, speed limit, and accidents. Moreover, other bunch of researchers preferred to select criteria such as travel time, risk level, and travel cost combined with MCDM models such as AHP, Data Envelopment Analysis (DEA), TOPSIS for route optimization [35].

In order to address both qualitative and quantitative decision factors in route selection improvement across complex transportation networks, there is a crucial need for an integrated framework. For instance, Koohathongsumrit and Meethom [36] presented a hybrid MCDM model that integrates the TOPSIS, AHP, and DEA for problem addressing based on qualitative and qualitative criteria. Other researchers, such as Hassannayebi et al. [37], applied the ELECTRE and Condorcet models to estimate bus service reliability utilizing multiple performance indicators. This research highlights the usefulness of fuzzy logic in managing the essential imprecision and uncertainty of transportation datasets. Another type of MCDM models demonstrates the use of weighting systems, both objective and subjective, to enhance route selection under diverse network conditions. For instance, Nie et al. [38] combined Multi-Attribute Decision Making with heuristic path search to enhance vehicular safety messaging. Moreover, Huang et al. [5] demonstrated an approach to adaptive route endorsement. This model uses a historical navigation dataset for user conducting modelling by employing a Deep-Cross-Recurrent learning model, which integrates both LSTM and DCN-v2 styles.

On the other hand, fuzzy MCDM techniques stand out due to their capability to cope with imprecise input data and linguistic variables [39] . This is particularly useful for modeling consumer preferences, levels of comfort, or safety perceptions, which are often difficult to quantify using accurate quantitative measures. Fuzzy logic techniques enhance the accuracy and adaptability of decision models, allowing them to more accurately represent the real-world complexity [40]. While the ability to capture the fluctuation and unpredictability of the driving route selection based on human participation, both hybrid MCDM and fuzzy techniques are increasingly becoming the preferred approaches in transportation planning [41].

Recent studies of traffic planning have facilitated the integration of MCDM models with factors that directly impact drivers' route selection. Beyond basic geographic considerations, optimal route selection using MCDM models should encompass dynamic variables like emission levels, fuel consumption, traffic volumes, accident rates, and vehicle speeds. These criteria enhance drivers' awareness and support alternative driving route selection [42]. For instance, algorithm weights can be adjusted by assigning more weight to safety (i.e., high-risk zones) than economy (i.e., fuel consumption) depending on circumstances or user preferences. In addition, decision quality can be improved by integrating various criteria into MCDM preferences, especially under rapid and uncertain fluctuating traffic scenarios. By developing the optimality of the route and aligning with broader objectives, this study offers a robust foundation for transportation planning and superior navigation [43].

Unlike prior studies that have approached MCDM with limited criteria, this research presents a WFJM and MULTIMOORA models with 12 criteria, like travel time, accidents, and geometric design of routes in addition to other criteria that highly impact the mood of drivers for route selection.

2 METHODOLOGY

This study suggests an organized three-phase methodology to address complicated decision-making scenarios, including multiple and occasionally conflicting criteria. The first phase develops the judgment/decision matrix along with the assessment criteria, guaranteeing the appropriate illustration of both quantitative and qualitative factors. Assessment of the expert and theoretical basis for process fulfillment is regarded as assembly integration. The second phase applies the WFJM to estimate the relative importance of criteria. By integrating expert input with fuzzy set theory, WFJM efficiently addresses bias and vagueness, converting ambiguous judgements into reliable numerical values. The last phase of methodology consists of applying the technique of MULTIMOORA, an improved version of Multi-Objective Optimization by Ratio Analysis (MOORA) that integrates the ratio system, reference point, and entire exponential procedures into a single robust framework. Besides, MULTIMOORA utilizes WFJM-derived weights for thorough ranking of alternatives, reducing bias and improving decision reliability. To provide an unambiguous, rigorous, and responsive decision-making procedure suitable for intricate estimation scenarios in unpredictable situations, the combination of these steps is crucial to implement.

2.1 Decision Matrix

The established judgement/decision matrix for this research acts as a fundamental structure for organizing the methodological and assessing the multiple selected routes for the investigation aspect. It comprises two primary components, judgment criteria and alternatives. Each of these components performs a distinct yet complementary purpose throughout the process of decision-making. The alternatives demonstrate the main segments of selected roads for comparison facets. Three essential segments of roads were selected for this research, each with particular topographical, functional, and structural characteristics. An essential freeway through the regional roads network, the first, a selected road segment of Expressway No. 1, is characterized by high mobility and strict access control. The second route option, named locally as Old Abu Ghuraib Road, acts as a crucial urban road and is mainly utilized by road users to drive between Baghdad and Fallujah. The third option is the Karmah Road, a major local route that links multiple neighborhoods by combining both urban and rural elements of transportation.

The second component of the assigned criteria indicates an array of characteristics or performance indicators against which each option is assessed. During the MCDM analysis, there are two crucial terms that should have been taken into consideration through analysis: cost (C) and benefit (B). The cost illustrates the criteria when lower values are desired, indicating cost, effort, or adverse effects that should be minimized through the decision-making process. In contrast, benefit depicts any criteria when higher values are desired, signifying benefits, advantages, or even positive effects that ought to be maximized over the process of decision-making. The designated criteria were selected due to their rank in terms of traffic performance, overall safety, environmental sustainability, and infrastructure resilience. These criteria were established based on a dataset comprising real field measurements, traffic and accident records, professional road inspections, and environmental surveillance data. The assigned criteria consist of the length of each selected road segment and travel time, defined as the average time required to traverse a selected road segment under specific conditions. Density is also one of these criteria, which illustrates the number of vehicles within an assigned length of the road. The speed limit

is also a crucial criterion when it is the maximum allowable speed that can be used by road users [44]. The rate of accidents is defined as the number of accidents per unit of time along a specified segment of the road [45]. The number of lanes and road surface conditions are also involved within the selected criteria at this study.

It is worth mentioning that the calculated criteria were collected during both selected peak AM (i.e., from 8:00 to 9:00 am) and PM (i.e., from 4:00 to 5:00 pm) periods. Each of these criteria was selected to reflect an imperative aspect of road performance, ensuring that the evaluation considered not only the efficiency of the trip, but also some factors such as safety, operational conditions, and environmental effect. By combining these multiple features into one neatly arranged decision matrix, this study presents a robust and unambiguous framework for elegant procedures of multicriteria decision making. This structure enables an organized assessment of different alternatives, besides improving the interpretation and consistency of analysis. These aspects are essential for establishing policies, infrastructure investment decisions, and further academic research on transportation system assessment.

The vital dataset utilized as criteria in this research consists of a bunch of key metrics. For instance, the reported number of accidents to law enforcement during a certain time period, by the length of the assigned road segment and the average speed of vehicles, was calculated by the floating car method. The selected data collection techniques guarantee accurate estimation, support successful transportation planning, and enable robust decision making.

Traffic density was performed manually by recording camera footage, when the observers review the recordings for vehicle counting passing through an assigned road segment during a specified time frame [46]. Consequently, traffic density was computed by dividing the number of observed vehicles by the length of the road segment. The determination of road condition was performed through site inspection, which offered an extensive estimation of pavement physical quality and related infrastructure.

Monitoring some factors, such as the existence of potholes, cracks, rutting, drainage efficiency, surface roughness, and shoulder conditions, was also performed within the inspection. The visual observations were frequently enhanced with defined assessment scales or indications of condition to recognize the extent and severity of deterioration [47].

The calculation of fuel consumption during peak hours was estimated by multiplying peak traffic volume, road segment length, and the number of peak traffic hours, then dividing by the assumed average fuel consumption efficiency factor for each vehicle (i.e., 10 km/l) [48]. The levels of pollution were estimated by using the road segment length, peak hours duration, and traffic volumes during peak hours. The latter values were multiplied by the CO_2 emission factor (i.e., 2.3 kg/l) and divided all by the average fuel efficiency of 10 km/l [49]. The resulting computation provides an estimate of the entire quantity of pollution that was generated during peak hours. This assists in understanding how traffic conditions impact the environment. Moreover, inspection surveys were conducted to identify all the remaining criteria, such as the existence of jersey barriers, the number of lanes, the presence of security checkpoints, and road lighting.

2.2 WFJM Method

The WFJM approach is principally divided into five stages. The first stage is like other MCDM models, in which the input consists of different sets of m alternatives (i.e., A1, A2, …, Am) along with n preferences of criteria (C1, C2, …, Cn). The intersection of criteria and alternatives is characterized as a decision matrix. Besides, the second stage, standardization, comprises utilizing the knowledge of experts to classify criteria as either cost or benefit types. The next step applies a normalization formula to the assigned values [50].

$$c_{ij} = \frac{c_{ij} - \min_i x_{ij}}{\max_i x_{ij} - \min_i x_{ij}} \text{ ; for benefit criterion} \quad (1)$$

$$c_{ij} = \frac{\max_i x_{ij} - c_{ij}}{\max_i x_{ij} - \min_i x_{ij}} \text{; for cost criterion} \quad (2)$$

The third stage comprises two steps: both expert identification and evaluation. The first step consists of selecting and recognizing professionals who have earned the confidence of their peers. In order to confirm availability and interest, selected experts were contacted via official email. The expert review and the development of an assessment form is regarded as the second step involved. In addition, this step comprises establishing an estimation form to gather expert input while ensuring its reliability and validity, which are of paramount importance.

The data transformation, the fourth stage, encompasses two steps. The first step involves identifying optimum values. There are three different classes of optimum values, regarded as the most feasible responses to this obligation. In some cases, the first group corresponds to higher values. For

instance, considering the grades of students, higher values correspond to better performance. In contrast, in the second case, the smallest value is the optimal. For instance, in network security concerns, smaller values are preferable. At the very least, some cases consist of optimum values that fall approximately in the middle range, like blood pressure. Hence, the recommended approach is crucial for addressing issues associated with varying weights in MCDM models. (3) illustrates the ideal solution.

$$A^{*} = \{((\max_i x_{ij} | x \in X) \cdot (\min_i x_{ij} | x \in X) \cdot (J_{ij} \in I.J) \mid i = 1.2.3 \ldots . m)\}. \quad (3)$$

In this context, max denotes the best optimum feasible value based on the advantageous criteria, while min illustrates the best potential value based on non-benefit criteria, and j_{ij} identify the critical quantity. Ideally, the optimal value lies within the range between the most extreme and the least extreme values. The subsequent stage entails comparing the best selected options against other alternatives. The outcome is a comparison of the best potential outcome for each criterion with other alternatives for the same criterion. In order to determine the alternative's deviation from the ideal alternative, weights are applied to reflect relative importance. Five linguistic metrics were utilized for comparison: big difference, huge difference, slight difference, and no difference. (4) depicts the mentioned process.

$$Op_{Lang} = \left\{\left(\begin{pmatrix}\tilde{x} \\ ij\end{pmatrix} \otimes x_{ij} \mid j \in J\right).\middle| \, i = 1.2.3 \ldots . m\right\} \quad (4)$$

In order to determine the best response and compare it to the other alternatives, $\otimes$ utilizes as the standard for comparison. The main theoretical basis for developing the assessment matrix is a comparison between the optimum and the alternative values under the same circumstances. Moreover, due to the development on the assessment matrix and evaluation within each criterion separately, the proposed system at this research has no inaccuracy.

Finally, the fifth stage involves employing the fuzzy function of membership. To improve the judgment matrix, the function of fuzzy membership is applied, followed by a defuzzification procedure. In order to ensure a logical procedure, these processes develop the practical precision and applicability of dataset usage. Nevertheless, imprecision and uncertainty may arise due to the challenges related to assigning weights to each criterion in MCDM models. Al-Hchaimi et. al [51] specified that utilizing fuzzy values instead of precise values enables better measurement of criterion significance, especially when addressing issues of fuzziness and ambiguity. Allowing decision-makers to express their viewpoint using linguistic variables is regarded as one of the benefits.

of Fuzzy Cognitive Systems (FCSs), especially when it enhances awareness and flexibility of experts. Moreover, for more realistic assessments of evaluated information, FCSs employ a boarder set of discrete points to present fuzziness and ambiguity in indeterminate concepts [52]. The theory of the fuzzy cloud can be defined using multiple classifications. The first definition, K is assumed as a qualitative concept belonging to a space Q. $x \in Q$ is regarded as a random recognition of K, satisfying $x \sim N$ (Ex, En2), and $En' \sim N$ (En, He2). $\mu T(x) \in [0, 1]$ is the convinced degree of x on K, which can be illustrated in equation (5):

$$\mu_K(x) = \exp\left(-\frac{(x - Ex)^2}{2(En')^2}\right) \quad (5)$$

The second definition states that D_1 = (Ex1, En1, He1) and $D_2 = (Ex_2, En_2, He_2)$ as a random cloud, while the value of λ is regarded as an actual value. The following outlines the principle of arithmetic operations, which can be illustrated as follows.

$$D_1 \pm D_2 = \left(Ex_1 \pm Ex_2, \sqrt{En_1^2 + En_2^2}, \sqrt{He_1^2 + He_2^2}\right) \quad (6)$$

$$D_1 \times D_2 = \left(Ex_1 Ex_2, |Ex_1 Ex_2| \times \sqrt{\left(\frac{En_1}{Ex_1}\right)^2 + \left(\frac{En_2}{Ex_2}\right)^2}, |Ex_1 Ex_2| \times \sqrt{\left(\frac{He_1}{Ex_1}\right)^2 + \left(\frac{He_2}{Ex_2}\right)^2}\right) \quad (7)$$

$$\frac{D_1}{D_2} = \left(\frac{Ex_1}{Ex_2}, \left|\frac{Ex_1}{Ex_2}\right| \times \sqrt{\left(\frac{En_1}{Ex_1}\right)^2 + \left(\frac{En_2}{Ex_2}\right)^2}, \left|\frac{Ex_1}{Ex_2}\right| \times \sqrt{\left(\frac{He_1}{Ex_1}\right)^2 + \left(\frac{He_2}{Ex_2}\right)^2}\right). \quad (8)$$

Table 1 illustrates the linguistic terms using FCS. In order to reach the optimum values for the estimation criteria (w_1, w_2, …, w_n) T of coefficient weights, the following steps are applied.

1) By combining equation 6 with the formally applied FCS formula, the fuzzification ratio dataset is determined, which can be denoted as A. For instance, the first criterion in the fuzzy representation can be illustrated as A_{C1}, and the second criterion is A_{C2}, which can be applied to the remaining criteria.
2) By applying the same procedure for all criteria, the summary of $\{A_{C1}, A_{C1}, A_{C1}\}/3$ can be utilized.
3) The obtained outcome of the above second step can be standardized by dividing it by the summation of the related results of the same

step, thereby providing the final criterion weight. Nevertheless, the weight should equal 1.0, as demonstrated in (9).

$$W = \frac{\left(\sum_{i=1}^{m} \frac{\left(\overline{(A_{cj})}\right)}{\left(\sum_{j=1}^{n} (A_{cj})\right)} \right)}{m} \quad \text{, for i} = 1,2,3, \ldots \text{m and j} = 1,2, \ldots \text{n.} \tag{9}$$

Table 1: Linguistic terms.

Linguistic terms	Nume-rical	Cloud value		
No_Difference (ND)	1	0.000	0.673	0.101
Slight_Difference (SD)	2	3.0988	0.453	0.068
Difference (D)	3	5.000	0.278	0.041
Big_Difference (BD)	4	8.262	0.579	0.086
Huge_Difference (HD)	5	10	0.673	0.101

2.3 MULTIMOORA Method

Through the analysis of ratios, a bunch of researchers have approached the optimization of the multi-objective optimization method (MOORA) [53]. In order to enhance its robustness, researchers extended this method by integrating a full multiplicative model with MOORA, known as MULTIMOORA [54]. This method has been applied in multiple domains of study, such as provincial assessments, cross-national evaluations, and investment management [55]. The MOORA method initiates with matrix X, where each entry x_ij indicates ith alternative associated with jth purpose (i = 1, 2,..,m; j = 1, 2..,,n). It involves two components: the ratio approach and the basis point approach. Brauers et al. [56] stated that the weighting methodology comprises two steps, depending on the relevance of outcomes. A bunch of other researchers have addressed the issue of normalization [57]. Moreover, other researchers have examined the issue of weighting [58]. The MULTIMOORA model focuses on internal standardization and treats all objectives equally. For instance, stakeholders associated with the topic might give a preference to a particular purpose. Hence, in order to depict a response on a target, either multiplying the dimensionless number, which reflects the response of the objective by an impact coefficient, or dividing the objective into multiple sub-objectives [59]. By comparing different options of objectives to different potential outcomes, MOORA's ratio system adjusts the dataset as illustrated in (10).

$$x_{ij}^{*} = \frac{x_{ij}}{\sqrt{\sum_{i=1}^{m} x_{ij}^{2}}}, \tag{10}$$

X_{ij} Represents the ith alternative for the Jth objective. In general, these values range between 0 and 1. In addition, criteria may be included or excluded based on their optimal value (i.e., minimum or maximum).

The considered index for every selection is calculated by (11).

$$y_{i}^{*} = \sum_{j=1}^{g} x_{ij}^{*} - \sum_{j=g+1}^{n} x_{ij}^{*} \tag{11}$$

It is worth mentioning that g signifies the number of objectives that should be maximized. At this stage, each ratio is assigned a rank, where a higher index corresponds to a higher rank.

The reference point approach in the MOORA is directly related to the ratio system. According to the specified ratios, (11) is utilized to determine the Maximal Objective Reference Point vector. The Jth coordinate of the reference point is expressed as rj = max(ix) in the optimization context. Each coordinate of this vector specifies the minimum or maximum value of a specific objective. Subsequently, each component of the normalized response matrix is calibrated accordingly. In addition, the final ranking is determined according to the deviation between the reference point and the minimum and/or maximum Metric as illustrated in (12).

$$\min_{i} \left(\max_{j} \left| r_{j} - x_{ij}^{*} \right| \right). \tag{12}$$

Updating the MOORA method was enhanced by Kreinovich and Cheu [60] through the integration of a full Multiplication Form methodology. This method consists of both optimizing and reducing the sole exponential utility function. The dimensionless quantity is regarded as the practical utility of the ith alternative, as illustrated in (13).

$$U_{i}' = \frac{A_{i}}{B_{i}}. \tag{13}$$

According to (13), A_i is defined as Πig=1 xij; i = 1; 2 where m represents the invention of the purposes that belong to the ith alternative to be maximized with g = 1, …, n. Also, Bi = Πig=1 X_{ij} Illustrates the objective product of the ith that is minimized with n

– g, the number of indications that should be minimized. It is crucial to mention that the MULTIMOORA includes both the full multiplicative form and MOORA components (Ratio Systems and Reference Points) [61].

3 RESULTS AND DISCUSSION

3.1 Results

According to the methodological approach described in the previous section, the analysis of the three main routes between Baghdad and Fallujah was conducted through a series of analytical stages. The results obtained for the selected road segments are presented below.

At the first stage, a decision matrix was constructed based on the selected evaluation criteria. This step was performed separately for the AM and PM peak periods to capture temporal variations in traffic conditions. The decision matrix is presented in Table A1 (Appendix) and serves as the basis for subsequent weighting and ranking procedures.

The weighting process was carried out using the WFJM method to determine the normalized importance of each criterion for both time periods (Figure 2). The results indicate that during the AM period, the most influential factors are speed limit (0.14245), road condition (0.11506), fuel consumption (0.11506), and pollution (0.11506), highlighting the importance of operational efficiency and environmental impact. Safety-related factors, such as accident frequency (0.07293) and road density (0.08748), also play a significant role due to congestion during morning hours. In contrast, factors such as checkpoints (0.03460) and jersey barriers (0.05830) have a lower impact.

In the PM period, the importance of lighting (0.17495) and road condition (0.11749) increases, reflecting greater concern for visibility and safety. While speed limit remains significant (0.11749), other factors such as road density, pollution, and fuel consumption show moderate influence. The increased weight of jersey barriers (0.08933) indicates higher safety requirements during evening travel. Overall, morning conditions emphasize efficiency, whereas evening conditions prioritize safety and visibility.

The ranking of alternatives was performed using the MULTIMOORA method. The evaluation combines three approaches—Ratio System, Reference Point, and Multiplicative Form—and aggregates the results using the Borda count (Table 2), ensuring a comprehensive and balanced decision-making process.

For the AM period, the Old Abu Ghuraib Route achieves the highest overall ranking with a Borda score of 8.0, despite not being the top performer in each individual method. This indicates consistent performance across all evaluation approaches. The Expressway Route and Karmah Route share the second position with equal scores.

In the PM period, the Old Abu Ghuraib Route maintains its leading position, confirming its stability across different time conditions. The Expressway Route ranks second, likely due to improved evening conditions such as lighting and traffic flow, while the Karmah Route ranks third due to less favorable conditions. Overall, the results demonstrate that the Old Abu Ghuraib Route is the most reliable and balanced option.

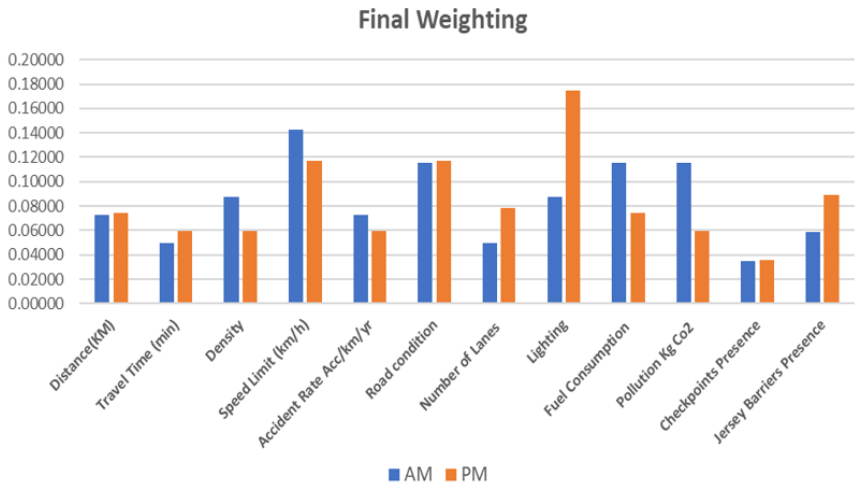

Figure 2: Final weight.

Table 2: Final rank.

Period	Path route	Ratio System	Reference Point	Multiplicative Form	Borda Score	Final Rank
AM	Expressway Route	1	3	1	5	2
	Old Abu Ghuraib Route	3	2	3	8	1
	Karmah Route	2	1	2	5	2
PM	Expressway Route	2	3	1	6	2
	Old Abu Ghuraib Route	3	2	3	8	1
	Karmah Route	1	2	2	5	3

3.2 Validation and Sensitivity Analysis

To verify the robustness and reliability of the obtained results, a sensitivity analysis was conducted (Figure 3). In this process, the weights of the evaluation criteria were systematically varied within a reasonable range, and the impact of these variations on the final ranking was examined.

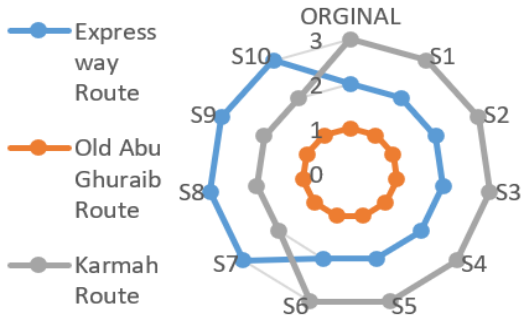

Figure 3: Sensitivity analysis.

The results show that the Old Abu Ghuraib Route consistently maintains the first position under both AM and PM conditions, even with significant changes in criteria weights. This stability indicates that the final decision is not overly sensitive to specific weighting schemes and confirms the robustness of the model.

Although minor ranking variations were observed for the Expressway and Karmah routes, these changes did not affect the overall ranking outcome. Therefore, the results obtained using the MULTIMOORA method can be considered reliable and consistent for decision-making purposes.

4 CONCLUSIONS

To utilize both the criterion dataset and expert judgement, a selected segment of Expressway No.1, the Old Abu Ghuraib Road, and the Karmah Road, regarded as the main social and economic arteries of road users between Baghdad and Fallujah, was subjected to thorough analysis in this study. Three methodological phases were taken into consideration for the complicated performance evaluation of the three selected routes (i.e., identification of the full set of criteria, assessing the significance of criteria by WFJM, and ranking the alternatives using MULTIMOORA approach.

Through three-phase integration, this study identified the route that operates best when the methodology is applied thoroughly and spatially accurately. Both AM and PM analyses of WFJM revealed temporal variations in the significance of the inspection criterion. For instance, during the AM period, environmental and operational factors like road condition, fuel consumption, speed limit, and pollution, combined with safety-related factors like accident frequency and traffic density, were the most significant. Conversely, the PM period emphasized visibility, safety, lighting, road condition, and the presence of jersey barriers as the most of significant criteria. Nevertheless, both environmental and traffic flow factors had an insignificant impact.

Based on MULTIMOORA analysis (i.e., ratio system, method of reference point, and Borda count aggregation for multiplicative form), the Old Abu Ghuraib Road was recognized as the ideal and the most reliable option for road users during both AM and PM circumstances. However, depending on the evaluation method and time period, both segments of Expressway No. 1 and the Karmah Road performed moderately but inconsistently. By confirming both stability and robustness of the final decision, the sensitivity analysis depicted that the Old Abu Ghuraib Road maintained its top ranking under different weighting conditions. Though all three selected routes are crucial for the regional transportation network, the Old Abu Ghuraib Road still performs best in terms of safety, operational efficiency, environmental impact, and infrastructural quality, despite temporal traffic variations.

Like others in the literature, this study has limitations. This paper studies only three selected routes that were evaluated based on the available data

and assessment criteria. However, a high percentage of drivers between Baghdad and Fallujah utilize these three selected routes. In addition to the traditional MCDM frameworks, such as Weighted Product Method (WPM), AHP, and Analytic Network Process (ANP), could have been employed, but the selected method offers specific advantages when it processes the inconsistency, one of the main gaps over the MCDM methods. For future studies, the research recommends adding another fuzzy with the methods used in this research. Also, incorporating criteria such as seasonal variations, environmental data, and broader socioeconomic effects into the MCDM framework could further route optimization. Moreover, integrating multi-model transportation systems and last-mile interactions would offer a much thorough perspective on urban mobility.

APPENDIX

Table A1 presents the decision matrix used in this study, summarizing the performance values of all three route alternatives across the selected criteria for both AM and PM peak periods. The matrix serves as the primary input for the WFJM weighting process and subsequent MULTIMOORA ranking analysis, ensuring a consistent and structured evaluation of route performance under varying traffic conditions.

Table A1: Decision matrix.

Ethical Risks and Improvement Potentials of AI Tools in Carbon Footprint Calculation: The Case of XAI

Din-Yuang Huang
Holistic Education Center, Graduate Institute of Educational Leadership and Development, Fu-Jen Catholic University, 24205 New Taipei, Taiwan

Keywords: AI Ethics, Carbon Footprint Calculation, Explainability, Transparency, Explainable AI (XAI), Sustainable Development.

Abstract: This study aims to explore the ethical risks from AI tools in carbon footprint calculation applications, especially focusing on Explainability and Transparency. Although AI provides convenient computing, the problem of "black box" may lead to a variety of ethical concerns caused by computing. This study first systematically reviews multiple documents and analyses to understand the initiatives for AI ethics and the risks arising from unexplainability and opacity. This study proposes Explainable Artificial Intelligence (XAI) as a solution to mitigate these ethical risks. The paper further explores how XAI can improve the transparency of carbon footprint calculation and its specific implementation by users through simulation of real-world scenarios. The Results show that XAI technology can transform AI's abstract predictions into mathematically rigorous and actionable evidence, enabling users to implement specific carbon reduction behaviours in their lives. Ultimately, this research contributes to the growing discourse on responsible AI by demonstrating how explainable models can foster trust, accountability, and sustainability in data-driven environmental decision-making.

1 INTRODUCTION

When we discuss the SDGs (Sustainable Development Goals) and ESG (Environmental, Social, and Governance), calculating carbon footprints is a crucial topic. For example, the ISO 1404X family of standards establishes a rigorous and comprehensive methodology, providing appropriate methods for different areas and yielding meaningful results. At the same time, many online carbon footprint calculators that provide personal carbon footprint calculations are used as calculation tools, and Generative AI (Hereinafter referred to as AI) can also be used to calculate the carbon footprint of personal life or organizations. AI technology has the potential to develop rapidly and be highly applicable in the field of sustainable development, especially in terms of carbon footprint calculation and optimization. As a convenient auxiliary tool, AI can provide a lot of important information and help users avoid complex calculations to obtain concise results.

While AI's efficiency comes with risks, we accept its output, but are AI's calculations biased? Are the results transparent within the AI's black box? Do the results adhere to the principles of sustainability and fairness? These issues, combined with human biases toward sustainability or green energy, can lead to biased judgments about the output. For example, Holmgren et al. conducted an experiment and found that people tend to incorporate compensatory green beliefs into less environmentally friendly objects, thereby lowering the calculated GHG CO2e values [1]. This reduced footprint may be due to averaging bias. Furthermore, regarding carbon footprint calculators, Murlow et al. noted in their research that these calculators vary greatly in details and boundaries and are often poorly designed to suit users. These AI operations can be subject to human error, leading to erroneous data output [2].

Based on questions above, this study aims to examine the ethical risks inherent in AI tools used in carbon footprint calculations. From an ethical perspective, this study examines how the concept of explainability impacts the reliability, credibility, and auditability of AI carbon footprint models. Furthermore, it addresses how data and algorithmic biases in AI carbon footprint calculations can lead to fairness issues, particularly in the attribution and

allocation of carbon emissions responsibility. Furthermore, based on these questions, this study explores how Explainable AI (XAI) technology can help avoid these ethical risks.

Before research begin, let's first define the boundaries and methods in this study. When discussing AI ethics, concepts like explainability, fairness, transparency, and accountability often come up. Since this study focuses on using AI tools for carbon footprint calculation, we will focus on the concepts of explainability and transparency. These two concepts are related to the calculation process, database, and coefficient selection when using AI to calculate carbon footprint. Since the purpose of this study is to clarify these two concepts and to demonstrate the importance of explainability and transparency through the help of the XAI model, this study does not attempt to develop a new and appropriate personal fitable model and only applies the XAI tools or models in practice. Secondly, to achieve this research result, this study will employ a literature review and synthesis method, as well as a conceptual analysis method, as the foundation for its thinking and research. This study will clarify the importance of these two concepts through a literature review, provide explanations and definitions for each, and then demonstrate their practical application and illustration using the XAI model.

2 LITERATURE REVIEW

The issues of explainability and transparency, along with the challenges posed by algorithmic "black box," have been central concerns since the earliest applications of AI tools. In this section, the literature is reviewed from three perspectives: the positions articulated by the United Nations and UNESCO, insights drawn from major trend reports, and contributions from academic scholarship. We will use the research method of Document Analysis to compare documents horizontally to clarify how different documents interpret explainability and transparency in AI, and whether these documents raise concerns about these concepts. This information will serve as the foundation for our discussion of these two concepts in Section 3.

Readers should pay attention here: the sources considered here are framed primarily within the educational domain. This orientation is deliberate, as carbon footprint calculation constitutes an integral component of Education for Sustainable Development (ESD). If processes of carbon accounting within the ESD context are marked by unexplainability and lack of transparency, the formulation of effective and contextually appropriate decarbonization strategies becomes considerably more difficult. In other words, without reliable interpretability in AI-supported assessments, sustainability education risks producing outcomes that are normatively appealing yet practically inadequate.

2.1 United Nations and UNESCO

The United Nations has, for several years, recognized the risks associated with AI "black box" and has emphasized the need for regulatory oversight of AI tools, particularly in relation to data governance. For instance, the *Ethical Impact Assessment: A Tool of the Recommendation on the Ethics of Artificial Intelligence* (2023) highlights explainability and transparency as essential requirements to ensure accountability. The objective of such regulation is to make explicit the logic and rationale underlying AI systems' outputs and decisions, thereby ensuring that this information is accessible and that users' trust can be strengthened [3].

By 2024, UNESCO extended its concern to the pedagogical context, focusing on potential issues that may arise when teachers and students engage with AI. In its proposed framework for developing teacher competencies, UNESCO underscored that AI outputs often carry elements of randomness. As a result, educators must develop an awareness of the black box nature of AI training processes and critically evaluate the results produced by such systems [4]. Moreover, the framework elaborates that explainability encompasses the languages used in training AI, cultural representativeness, methods of data collection and utilization, as well as the adaptability of AI systems to learners of different ages and abilities [4].

With regard to students, UNESCO recommended that learners be made aware of their right to request information concerning explainability from system designers and providers [5]. Such awareness, it argued, forms a foundational competency of a human-centered mindset [5]. Similarly, in the Governing AI for Humanity: Final Report, the United Nations emphasized that AI technologies are frequently characterized by opacity and deficiencies in interpretability [6]. The report further urged member states to advance research into the transparency of AI, thereby mitigating the risk of outcomes or decisions that may exceed human capacity for responsibility or redress [6].

Most recently, in 2025, UNESCO introduced additional guidance for the academic use of AI. The report *Guidance for Generative AI in Education and Research* explicitly acknowledged the longstanding challenge: "It has long been recognized that artificial neural networks (ANNs) are usually 'black box'; that is, that their inner workings are not open to inspection. As a result, ANNs are not 'transparent' or 'explainable', and it is not possible to ascertain how their outputs were determined" [7]. Consequently, UNESCO recommended that AI providers disclose trustworthy data and computational models, including the provenance of data, the modeling techniques employed, and the types of algorithms used, thereby ensuring both explainability and transparency for end-users [7].

2.2 Recommendations and Cautions in Trend Reports

Beyond the contributions of the United Nations and UNESCO, numerous foundations and research institutions with a focus on education regularly publish reports on AI-related issues. Many of these reports likewise highlight concerns regarding the "black box" nature of AI systems and offer recommendations for mitigating associated risks.

In a report on the ethical risks of AI prepared for SURF in the Netherlands, Sack and Little observed that AI tools pose threats to fairness and justice, one major cause being the underlying algorithms themselves. Such algorithms may perpetuate biases or enable exploitative practices [8]. Similarly, Molina and Medina, in a report commissioned by the World Bank on the use of AI in higher education across South America, argued that the lack of transparency in AI tools obstructs the effective promotion of certain professional practices and constrains the optimal use of AI. They further noted that algorithmic biases can produce inequitable outcomes [9]. They identified seven potential sources of bias, among which "Data Collection and Preparation" and "Problem Definition" are particularly relevant to the domain of carbon emission calculation [9].

Hoernig and colleagues, in a report for the Lisbon Institute of Public Policy, similarly emphasized that one of the primary harms of AI use is the lack of explainability and transparency. From an educational standpoint, they argued, users must first confront the problem of AI black box in order to monitor algorithmic bias, design curricula, or integrate AI responsibly into instruction [10]. The report also noted that the European Union's AI Act already requires disclosure of AI outputs and calls for measures to mitigate risks stemming from inadequate explainability and transparency, including training to identify bias [10].

In the United States, the Department of Education's Office of Educational Technology underscored similar concerns in its 2023 report. Cardona et al. emphasized the importance of enhancing transparency and providing explicit disclosure of relevant information [11]. They recommended the development of integrated AI policies grounded in ethical and just principles, with "Promote Transparency" identified as a core pillar [11]. Moreover, the report advocated for the adoption of inspectable, explainable, and overridable AI in educational contexts. Such systems would enable teachers to understand how AI evaluates student work, why it recommends certain resources, and the rationale behind specific pedagogical suggestions [11].

2.3 Other Categories of Literature

Many scholars have also mentioned the importance of ethical characteristics such as AI explainability and transparency. For example, Pikhart and Al-Obaydi (2025) interviewed teachers and mentioned that the respondents expressed concerns about the validity and reliability of AI data [12]. These concerns include the belief that AI data may contain inaccuracies or erroneous information and the need for further verification [10]. Even those respondents who acknowledged that AI data has some reliability believe that verifying the information is important because AI can produce data that is difficult to assess for accuracy. These respondents generally believe that data generated by AI is generally unreliable. Vasquez III et al. note that AI algorithms can be subject to bias and potentially lead to unfairness, emphasizing that potential biases should be carefully considered when developing AI and its algorithms. Furthermore, attention should be paid to the lack of transparency in AI's decision-making process [13]. Vredenburgh (2024)'s research on the application of AI in public policy emphasizes that AI should be transparent to avoid harm to human rights in politics or justice [14].

To sum up, explainability and transparency of AI are important because these two ethical qualities affect every aspect of our daily lives. From the perspective of carbon emission calculations, these two characteristics are not only related to whether the calculation process can produce reasonable conclusions, but also to whether the results obtained due to this unclear process will cause harm to the user.

The reviewed literature highlights the central importance of AI explainability and transparency within the domains of education and sustainable development. The United Nations and UNESCO emphasize that, in order to uphold ethical use and accountability, the decision-making logic and computational processes of AI systems must remain understandable and accessible. Trend reports further caution that algorithmic bias and opacity may compromise fairness, and that for both educators and students, understanding the "black box" characteristics of AI is essential to safeguarding the quality of teaching and learning. Academic studies corroborate this perspective, noting that lack of transparency in AI data, reliability, and public policy applications can produce potential harms for users and society. From the perspective of carbon footprint calculation, these ethical attributes affect not only the reasonableness of computational processes but also the potential risks of adverse outcomes for users. Overall, the literature underscores that maintaining explainability and transparency in AI-supported carbon footprint assessment is foundational to ensuring ethical rigor, auditability, and fairness.

3 ON THE CONCEPTS OF EXPLAINABILITY AND TRANSPARENCY

Based on the preceding literature analysis, we have established that explainability and transparency are of critical importance for AI. The question that follows is: how should these two concepts themselves be explained? In other words, how can the concepts of explainability and transparency be rendered explainable and transparent?

Vredenburgh (2024), drawing on Kafka's novel The Trial, illustrates the dangers of untransparency and unexplainability: the protagonist is arrested, yet neither he nor anyone else knows the reason for his arrest. Although everyone insists he must be guilty, no one can specify his crime [14]. This allegory reflects the problem of AI "black box." Vredenburgh argues that explainability refers to the capacity of inference models to be understood by users. Using decision trees as an example, he notes that the branching nodes of decisions should be traceable; in this sense, AI outputs can be considered transparent. Vredenburgh thus situates these terms within the domain of political philosophy. Balasubramaniam et al. (2023) approach the concepts from an ethical standpoint, viewing transparency as a non-functional requirement that is nonetheless crucial due to its dependence on trust within system development. Both explainability and transparency are context-dependent and require careful attention to ethical principles in real-world applications [15].

The findings of Vredenburgh and Balasubramaniam align with Palacio et al. (2021), who note that although these concepts are widely regarded as important, there is no universally accepted standard, and their interpretation and application remain diverse [16]. This plurality affords significant flexibility for the design of XAI. Palacio et al. ultimately define explanation as "the process of describing one or more facts, such that it facilitates the understanding of aspects related to said facts (by a human consumer)." Compared to the previous two studies, this definition similarly emphasizes the process of being understood, though the focus differs across contexts. These conceptual insights resonate with Fedytskyi's (2025) discussion of transparency, which highlights its relation to data bias and decision-making processes. Both terms relate to the reference process users use to make decisions [17].

The above description is similar to the OECD's definition of explainability and transparency in Section 1.3 of The OECD Recommendation on AI [18]. In the web version, the OECD provides us with further explanation. Transparency emphasizes the disclosure of information during interactions, allowing users to understand AI's operations and obtain meaningful information to make more informed choices. It also promotes public and stakeholder understanding. Regarding explainability, the OECD states that "explainability means enabling people affected by the outcome of an AI system to understand how it arrived at." [19]

According to this, and considering that this research is related to carbon footprint calculation, whether the user is motivated by sustainable development education or practical needs such as carbon inventory work, when we use the terms explainability and transparency, we will primarily focus on ensuring that the AI coefficient selection and operation process can be understood. The former emphasizes the calculation process, while the latter means the source of the selected coefficients or database: both are important bases in carbon emission calculations. In our research, we will specifically consider transparency because it concerns the fairness of the calculation base and results. The 2023 EDPS (European Data Protection Supervisor) report mentioned, "The concepts of transparency, interpretability and explainability in the context of AI have no formal definition, and are sometimes used

interchangeably." [20] And according to EDPS, "A transparent AI system enables accountability by allowing stakeholders to validate and audit its decision-making processes, detect biases or unfairness, and ensure that the system is operating in alignment with ethical standards and legal requirements." [20] This is because it concerns whether the coefficients and regulations selected by AI when calculating carbon footprints are available for users to review. As for another common word, interpretability, we will not discuss it in this study because it is related to the interpretation of results rather than the actual calculation of AI when calculating carbon footprint

4 ETHICAL RISK ANALYSIS OF AI TOOLS IN CARBON FOOTPRINT CALCULATION

Building on the results of the preceding literature review, we examined how scholars have explained the concepts of explainability and transparency, both of which are primarily tied to the computational processes involved in the use of AI [21]. For example, in the case of Taiwan, the implementation of organizational carbon inventories is typically guided by five foundational steps in training and education: defining boundaries, identifying sources, performing calculations, reporting, and verification [21]. Beyond the act of calculation itself, both boundary setting and source identification are directly related to methodological choices and the selection of coefficients. If AI systems fail to provide adequate reference materials, users are exposed to the risk of being unable to discern the reliability of the data produced.

4.1 Ethical Characteristics of AI

Within ethical frameworks, AI is expected to embody, though not be limited to, the following characteristics: explainability, fairness, transparency, accountability, privacy, and security. UNESCO's thical recommendations highlight that AI-generated outcomes must not cause harm, nor should AI-driven decisions lead to irreversible consequences [3]. Although the report primarily references life-and-death decision-making scenarios, the principle holds equal importance in carbon footprint calculations, as such computations directly inform strategic planning, policy decisions, and financial commitments to emission reduction [3]. When AI ethics link transparency and explainability to accountability and responsibility, they entail whether sufficient explanations are provided to facilitate user understanding, and whether algorithms and internal reasoning processes are disclosed to the public or regulatory authorities as part of essential information transparency.

One of the primary ethical risks in using AI for carbon footprint calculations is the lack of explainability. Carbon footprints can be computed through categorical classification and subsequently presented as numerical data in public documents such as sustainability reports. However, for users lacking specialized training in carbon inventory methodologies, the calculation process and classification methods are often not their primary concern. Instead, they focus on the outcomes and numerical results, which guide their decisions in autonomous emission reduction efforts. In such contexts, transparency and explainability in the computational process demand a greater degree of trust. Therefore, when using AI tools to conduct carbon inventories, in the absence of coefficients, supporting information, and calculation processes, the data obtained poses a certain degree of risk from an ethical perspective.

4.2 The Case of Carbon Footprint Calculators

Now we can take the example of a carbon footprint calculator to illustrate the impact of this lack of interpretability risk. The carbon footprint calculator is a simple tool that helps people understand the carbon emissions generated by their activities. It has appeared on the Internet many years ago. By setting and inputting conditions, users can easily calculate the CO2e GHG they produce within a certain period of time. The carbon footprint calculator is widely accepted by users because it avoids complicated calculation processes and can obtain the corresponding carbon emissions simply by inputting the activity figures.

Although such calculators are user-friendly, reducing human activity into a formula for quantitative computation is not a straightforward task. As early as a decade ago, West et al. (2015) pointed out the inherent complexity of these calculations and their connection to behavioral change [22]. They suggested that future designs should account for changes in product prices and emission factors over time, as such changes may render the underlying methodology outdated. Designers must also navigate the trade-off between precision and usability.

Excessive complexity in data entry, pursued in the name of accuracy, risks deterring user participation.

From a user-centered perspective, Williamson (2022) reported the question which we call the "black box problem" [23]. Based on her experience, the annual household carbon footprint estimated for her family ranged from 8 to 42 tons of CO2e, depending on the level of detail in different calculators. She observed that different tools draw on varying datasets and assumptions, yet these assumptions rarely capture the specific lifestyle of an individual user relative to national averages. This underscores the necessity for calculators to provide transparent and sufficient data, references, and disclosure of computational processes.

DuPuis and Mulvaney (2024) mentioned the black box problem of this carbon footprint calculation. Although the carbon footprint calculator is a simple and convenience tool, it has been criticized on three problems: issues of accuracy and completeness in its design, its effectiveness in achieving the goal of changing individual behavior, and related scientific research issues in climate governance [24]. The first of these is related to the opacity issue mentioned in this article; the inaccuracies of carbon footprint calculators include inconsistent results, a lack of transparency into the data sources used in their algorithms, and errors even in the data used for reference. Taking meat calculations as an example, they pointed out that factors ignored by carbon footprint calculators lead to differences in carbon footprint calculations. Such differences may cause the calculation results to be distorted, and ultimately it is difficult to provide practical help for global emission reduction efforts.

The impact is not just about the difference in the calculation results, but also about applying the results to possible wrong decisions in life. Improper design of carbon reduction methods, or increasing emission reduction efforts in areas where emission reduction results are not significant, will affect the adoption and implementation of emission reduction strategies. If the carbon footprint calculator website used has a payment mechanism where users can donate to help reduce emissions, how should users ensure that their quota is in line with actual results? Therefore, the black box aspects of carbon footprint calculations in AI applications include difficulties in auditing and verification, particularly in understanding why AI models produce specific carbon footprint values. Furthermore, when no reference coefficient for emissions reduction is specified, the AI can be tricky to understand which data sources it uses to generate its results. Due to the difficulty of auditing and verification, it is difficult for users to assess whether they are biased by data, sampling or measurement, thus giving rise to fairness issues.

These ethical challenges are related to opacity and the absence of explainability, which also blur accountability and responsibility. While UNESCO's Ethical Impact Assessment framework provides a template for evaluation [3], its effective application depends on both AI developers and users proactively engaging in self-assessment. Yet when AI systems generate erroneous results or cause ethical harms, the unresolved question remains: who bears responsibility - the data providers, AI developers, model deployers, or the end-users?

5 XAI AS AN ETHICAL SOLUTION TO THE BLACK-BOX PROBLEM IN CARBON FOOTPRINT CALCULATION

As discussed earlier, the issue of the "black box" in AI decision-making poses significant ethical challenges. Because carbon footprint calculation involves the use of reference coefficients and the specification of contextual conditions, employing AI as a computational tool may generate discrepancies in outcomes - particularly when users are unable to clearly define all scopes, categories, and conditions. In such cases, whether through simplified carbon footprint calculators or AI-based computational frameworks, the results may vary substantially. To address these black-box concerns in carbon footprint analysis, the introduction of Explainable AI (XAI) offers a potential pathway for mitigating these ethical dilemmas.

5.1 The Concept of XAI

Taking IBM as an example, the company defines XAI as "a set of processes and methods that allows human users to comprehend and trust the results and output created by machine learning algorithms." According to this perspective, predictions must be accurate, the underlying techniques should be traceable, and the decision-making processes must adequately meet human needs. Proper use of XAI can enhance users' confidence in the outputs while simultaneously assisting designers in building and planning AI models with a sense of responsibility. In this respect, XAI is regarded as a key enabler of responsible AI, positioning AI models within a framework of trust and transparency [25].

EDPS further highlights that XAI embodies transparency, interpretability, and explainability – features that help users evaluate decision-making processes and understand the principles behind model predictions. EDPS also identifies two modes through which XAI facilitates interpretability in AI tools [20]:

- White Box: Employing simple and understandable models (e.g., decision trees or linear regression) that provide clear explanations of decision logic, thereby allowing decision-makers to grasp the rationale underlying specific outcomes.
- Post-hoc Explanations for Black Box Models: Offering retrospective explanations of decision processes. These include local explanations such as LIME (Local Interpretable Model-Agnostic Explanations) and SHAP (SHapley Additive exPlanations), as well as global explanations that provide broader interpretive frameworks.

Management Solutions also defines XAI as "a set of processes and methods that enable users to understand and trust the results and products created by machine learning algorithms. This discipline is crucial for an organization to build trust when using AI models, helping to characterize model accuracy, fairness, transparency and understanding of results in AI-based decision making" [26]. Their report further distinguishes between "interpretability" and "explainability." The former emphasizes human-centered understanding, defined as "the ability to explain or present in terms that are understandable to a human being," and refers to the degree to which a person can grasp the cause of a decision. The latter, in contrast, focuses on algorithms and internal logics, defined as "the dimension of a model output that describes how the output of the model was produced," demonstrating the extent to which the internal mechanics of a machine learning system can be expressed in human terms [26].

In sum, XAI may be concisely described as an approach that distinguishes itself from conventional AI by ensuring that the information it generates is interpretable and that its processes of outcome generation and decision-making can be rendered intelligible. XAI thus embodies the explainability and transparency that contemporary discourse expects from ethically responsible AI systems.

5.2 Is Such an Operation Ethically Sound?

If we apply the concept of XAI to carbon footprint calculation, and recall the discussion in Section 4.2 where the carbon calculator was used as an example, the importance of explainability and transparency in carbon accounting becomes evident. XAI, when integrated into carbon footprint calculation, should allow users to trace the sources of coefficient references, or at the very least, help them understand why AI recommends a particular mitigation strategy.

Drawing upon the three procedural steps in carbon accounting – boundary definition, source identification, and calculation – XAI's transparency primarily facilitates bias detection and diagnostic assessment. When XAI can reveal variations in model performance across different data subsets (such as geographical regions, income groups, or industrial sectors), users can scrutinize whether unfair coefficient references exist or whether location-specific sensitivities have been properly accounted for. As highlighted in the United Nations' Governing AI for Humanity: Final Report (2024), AI governance is far from evenly distributed worldwide. For instance, among 54 African countries, 48 were reported in 2024 to lack adequate AI governance mechanisms [6].

The distinctive features of XAI can provide substantial support in this context. When data inputs are adaptively trained and model algorithms optimized, users can access more accurate information and results regarding carbon footprint calculations. Enhanced precision not only improves trust but also increases the acceptability of the outcomes. Particularly significant is the capacity of XAI to furnish a "chain of evidence" in model decision-making. This includes documentation of data sources, coefficient selection, boundary settings, and constraints – key elements in carbon accounting. Such mechanisms enable AI to provide more reliable and consistent explanations, thereby helping to avoid potential greenwashing practices in carbon reporting.

In this way, by enhancing both explainability and transparency, the data produced by AI systems gains qualities of accountability and traceability. These qualities are indispensable for meeting the ethical requirements imposed on the use of AI in carbon footprint calculations.

5.3 Example: Does a Clearer Calculation Process Enhance Explainability?

Building on the concepts previously outlined, if explainability and transparency are integrated into carbon footprint calculation, users will be able to verify the ethical responsibilities tied to

accountability. In this section, two illustrative cases are used to advance the discussion:

1) Does employing the most recent version of ChatGPT-5 for carbon footprint calculations enhance the possibility of generating comprehensible results?
2) Does the use of XAI techniques – such as LIME and SHAP – offer more meaningful outcomes in carbon accounting?

Both cases are based on a carbon reduction project carried out and supervised by the author during an academic conference held in June 2025. One of the author's responsibilities in this conference was to establish a baseline for the event's carbon emissions, so that similar large-scale events in the future could benefit from a standardized reference for carbon footprint assessments. For this purpose, the research team employed Gemini to construct the computational model and adhered to ISO 14064-1 to categorize potential carbon emissions into six distinct categories. The resulting calculations were subsequently cross-verified using ChatGPT-4.

5.3.1 A Clearer Calculation Process

Taking ChatGPT as an example, in August 2025 OpenAI released GPT-5, which provides enhanced computational capacities. On August 10, 2025, the author conducted a comparative inquiry into the two versions, with particular attention given to whether GPT-5 exhibited operational features consistent with XAI principles. The test case involved paper lunchbox recycling, which was one of the subprojects in the aforementioned conference. During the event, the working team collected and recycled a total of 633 paper lunchboxes. The results highlight the differences between GPT-4 and GPT-5 in carbon emission calculations.

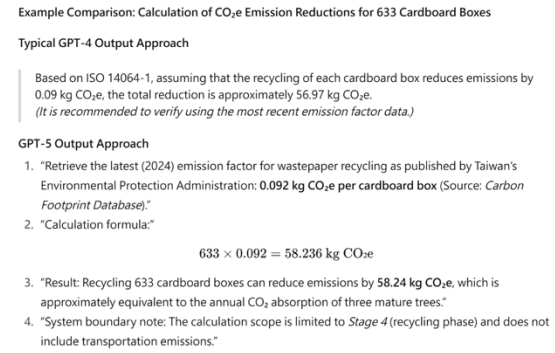

Figure 1: The example of differences between GPT-4 and GPT-5 in carbon emission calculation.

The above chart illustrates the computational differences between GPT-4 and GPT-5. While both algorithms compute "633 recycled cartons," the computational process and content presented differ significantly. Using GPT-4, we can directly obtain the basis and results of the calculation, but without the computational process and its limitations. Whereas GPT-5 went further by offering not only the basis and results but also the explicit calculation formulas and system boundary settings. Particular attention should be directed toward the notion of system boundary. This is a critical step in carbon footprint assessment, corresponding to the "boundary" concept discussed earlier. As shown in GPT-5's output (point 4 in the figure), the results are constrained within Stage 4, thereby offering substantial support and evidence regarding whether transportation should be incorporated into the calculations. This feature enables users to more clearly distinguish the categories of emissions, thereby enhancing both the clarity and accountability of the carbon accounting process.

5.3.2 Application of LIME and SHAP Models

The calculation process in Figure 1 above provides an example of transparency. Introducing LIME and SHAP can also enhance our understanding of data. This relates to the concept of interpretability, that is, whether data can be understood in a more reasonable way. This forms the second case study presented in this research.

This paper does not delve into the principles of LIME and SHAP. Related explanations can be found in the earlier discussion of XAI [26]. We can also build upon the statements made by Dwivedi and his team [27]: both methods are characterized by their ability to provide interpretations that measure the impact of having a certain value for a given feature in comparison to the prediction. Thus, when data is produced, it is no longer just numbers or results, but rather a set of symbols that can be understood and given meaning.

In this section, regarding the calculation of conference-related carbon emissions, we use Stage 3: Carbon emissions from commuting as an example. Based on Gemini's calculation results, the researcher can compare the reasonably expected amounts of carbon emissions. For instance, a scenario may be set up comparing driving a 2000cc gasoline SUV from Taichung, Taiwan, with traveling by high-speed rail. Traditional data would only provide raw figures, such as the estimated CO2 emissions produced by driving

the vehicle. However, by incorporating LIME and SHAP, the analysis can be extended to include driving habits, thus providing more meaningful explanatory insights.

We can compare scenarios constructed by SHAP: for example, comparing aggressive driving with taking the high-speed rail. If we assume a driver tends to drive aggressively, coupled with a vehicle of higher engine displacement, the total carbon emissions for a single trip could reach 28 kg CO2e. In contrast, traveling by high-speed rail would result in only 3 kg CO2e. The choice of "mode of transportation" offsets most of the emissions. When these two approaches are compared, it becomes possible to quantify and evaluate the environmental benefits of choosing high-speed rail, providing strong persuasive power.

5.4 Why Is XAI Important for Carbon Footprint Calculation? Ethical Reflections

In the two examples discussed in Sections 5.3.1 and 5.3.2, we observed that XAI provides us with clearer and more explicit explanations, making the interpretation of data more meaningful. For instance, in the case of carbon emissions from driving, if the data is merely explained at a numerical level, it does not inherently carry accountability. However, when the SHAP model is applied, the data becomes directly linked to vehicle engine displacement and driving behavior. This kind of modeling not only resonates with users but also prepares the groundwork for future carbon-related transactions by ensuring that the outcomes are understandable and fair for trading.

An article published on the Sustainability Director website reminds us that XAI has significant implications for carbon pricing. The transparency of carbon pricing implies data disclosure, and under such circumstances, it builds our understanding of and trust in mechanisms for sustainable economic transitions. XAI can provide the transparency required for carbon pricing: through its application, it can certify the transparency of the origin of carbon credits. Since XAI can offer the necessary tools and techniques to address transparency challenges in the field of carbon pricing – through evaluating carbon sequestration projects, collecting and processing complex datasets, and ensuring accountability in carbon price setting – it establishes a rigorous methodological foundation for high-quality, reliable data. This introduction of XAI provides quality-assured data through rigorous methodologies and user-centric design, ensuring that different users receive the most appropriate data. This article also addresses the issue of transparency atrophy, meaning that even with XAI, black box migrations can still occur [28].

In this sense, the use of XAI in carbon footprint calculation, based on its properties of explainability and transparency, creates the possibility of accountability and fairness in the outcomes. Thus, the introduction of XAI into carbon footprint assessment can meet ethical requirements in its application.

6 CONCLUSIONS

Since carbon footprint calculation is an essential component of sustainable development, obtaining reliable data becomes critically important. Reliable data requires clarity regarding database sources, the use of accurate and verifiable coefficients, and a transparent and reviewable calculation process. We cannot demand that every user undergo professional training or obtain certification before engaging in carbon reduction efforts, because such practices are a vital part of sustainability education and should be accessible as actions that anyone can take in daily life. Therefore, when using AI as an assistive tool, AI with explainability and transparency becomes particularly important: users need to understand how their data is generated, so that they can in turn understand how to take concrete actions to reduce emissions.

In discussing the introduction of XAI as a support for carbon footprint calculation, this study argues that explainability and transparency are crucial when using AI tools, and that XAI has the potential to meet these requirements (though its effectiveness still depends on users' professional competence and the depth of the instructions provided). While this paper used LIME and SHAP as examples of XAI applied to carbon footprint calculation, these cases are only preliminary illustrations. Future research could explore how to deepen the application of XAI or even develop new XAI methods better suited for environmental data and carbon footprint models. Furthermore, due to the limitations of this study, the concept of interpretability was not addressed in detail – only briefly referenced in examples. Since this concept relates to fairness, justice, and accountability, it is recommended for future dedicated research.

The integration of XAI technologies in the future will not only provide data with explainability and transparency in carbon footprint calculations, but also – through comparisons of different models – help users understand how they can implement emission reduction strategies in real life and even enable them to clearly measure the actual numerical outcomes of

their carbon reduction efforts. For this study was based on document analysis, while it provided some conceptual clarity, the limited AI experimentation left some room for improvement. Future research is recommended to conduct qualitative interviews to understand user experiences and design more comprehensive experiments. Through actual AI implementation and analysis of the results, we can understand how the introduction of XAI improves the concepts of explainability and transparency.

Keywords: Government Employees, Job Satisfaction, Macroergonomics, Public Sector, Public Service Motivation.

Abstract: This study examines the relationships among job demands, job resources, job satisfaction, organizational commitment, and job productivity within the public sector. Grounded in the Job Demands–Resources (JD-R) framework, the research investigates how work-related factors and personal resources influence employee attitudes and performance outcomes. Using survey data collected from public servants, structural equation modeling (SEM) was employed to test the proposed hypotheses. The results indicate that job demands significantly influence job satisfaction, while job resources contribute positively to both job satisfaction and organizational commitment. Organizational commitment was found to mediate the relationship between job satisfaction and job productivity, confirming its central role in translating employee attitudes into performance outcomes. In contrast, psychological safety and public service motivation did not demonstrate statistically significant effects within the final model and were excluded from further analysis. These findings suggest that, in this context, structural and organizational factors play a more substantial role than individual motivational constructs. The study highlights the importance of strengthening job resources and fostering supportive work environments to enhance employee satisfaction, commitment, and productivity in public sector organizations. Practical implications include the need for management strategies that prioritize resource availability, role clarity, and employee engagement to improve organizational performance.

1 INTRODUCTION

Public service plays a critical role in delivering essential services such as healthcare, education, and transportation, making it a noble profession tied to national development. Many employees enter government driven by a sense of duty to the public good, linking their work to a greater purpose [1]. However, job satisfaction is critical to maintaining motivation and performance. Motivated public servants contribute to effective governance, economic progress, and public trust [2]. In the Philippine context, due to challenging problems like insufficient wages and poor working conditions job satisfaction issues are evident [3]. With this, public service quality is affected as well as organizational commitment.

In the Philippines, only 1.66% of the population represents the public servants, this small percentage makes their role critical [4]. Despite this, most experienced lack appreciation and support from the public. In addition, Filipino government workers, whose perception is negative due to political patronage and high corruption index which is in contrast India, where government jobs are honorable [5]. Additionally, they have their social and financial lives restricted by job status such as contractual employment and therefore demotivate them further [6]. With this, declination of public service motivation and low job satisfaction are affecting their job productivity.

Public Service Motivation (PSM) theory is a source of personal values that drive public employees to excel in public service. To add, high PSM levels correlate to high job satisfaction and linked performance and commitment [7]. But in developing nations such as the Philippines, PSM is not sufficient to analyze the work outcomes in scenarios where poor research production and corruption issues are prevalent [8].

In addition, other existing models that manage aspects such as recognition, job engagement, rewards, and work-life integration [9]. This study integrated PSM frameworks and macroergonomics domain

through PLS-SEM analysis to determine their influence on job satisfaction and productivity in the government. The results aim to provide the Philippine public sector with civil service policies and reforms through improving human resources and guiding future research.

2 CONCEPTUAL FRAMEWORK

This study integrates macroergonomic domains like job resources and personal resources, public service motivation (PSM) theory which is shown in Figure 1. The framework consists of 14 first-order latent variables: rewards/compensation (RC), recognition (RE), job opportunity (JO), job enrichment (JEN), job rotation (JR), organizational identification (OI), job demand (JD), psychological safety (PS), perceived organizational support (POS), public service motivation (PSM), job engagement (JE), organizational commitment (OC), job satisfaction (JS), and job productivity (JP). To which, 7 hypotheses were created. Furthermore, this integration extends PSM theory by incorporating macroergonomic perspectives in an organization through the motivational drivers to influence job satisfaction, commitment, and productivity in the public sector context.

2.1 Challenges to Job Satisfaction and Productivity in Philippine Public Service

Job resources are critical factors that enhance employee satisfaction by providing both tangible and intangible support in the work place.

- Rewards/Compensation (RC). Refers to financial incentives, salaries, and benefits that influence employee satisfaction.
- Recognition (RE). The formal or informal appreciation to which employee contributions are acknowledged.
- Job Opportunity (JO). Chances for career advancement and internal promotion.
- Job Enrichment (JEN). Which roles are meaningful, and challenging which provides opportunities for skill development.
- Job Rotation (JR). The availability of different roles or tasks that reduce.
- Organizational Identification (OI). Employees align with the organization's values and mission.

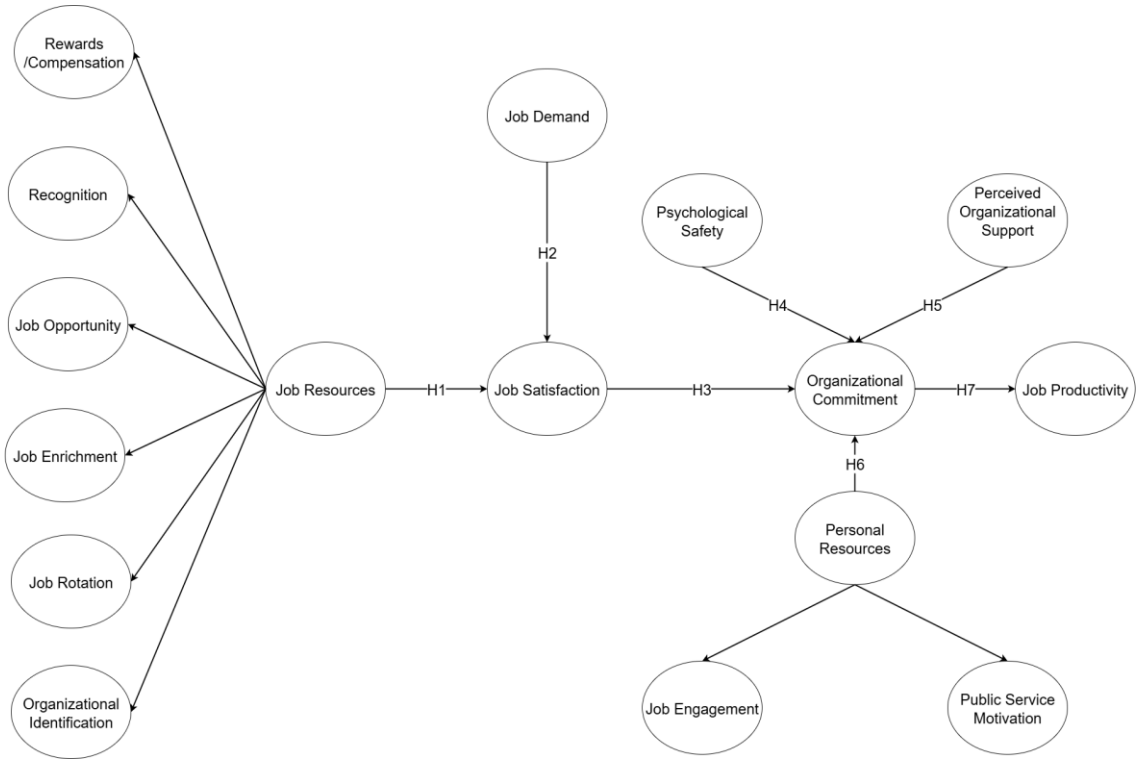

Figure 1: Conceptual framework.

- Job Demand (JD). Workload perceived by employees whether psychological or physical, which may influence stress and satisfaction.
- Psychological Safety (PS). Allows open communication in the work environment without fear of negative consequences.
- Perceived Organizational Support (POS). Employees in their organization sense that it prioritizes their well-being and acknowledges their contributions.

Personal resources are essential drivers of organizational commitment, as they shape the extent to which employees identify with their work and organization.

- Job Engagement (JE). The emotional and cognitive connection an employee has with their work.
- Public Service Motivation (PSM). The intrinsic desire to prioritize community welfare over personal gain.
- Job Satisfaction (JS). A positive affective state derived from perceived fulfillment experience from a job.
- Organizational Commitment (OC). Employees' attachment to their organization means emotional and loyalty.
- Job Productivity (JP). The effectiveness of employees in achieving work-related outputs.

2.2 Hypotheses

Based on the theoretical framework discussed, the following hypotheses were formulated:

1) H1: Job resources such as rewards and compensation, recognition, job enrichment, job opportunity, job rotation, and organizational identification are essential to improving employee satisfaction. Research in rewards/compensation using thorough compensation demonstrates that a feeling of equity in compensation improves job satisfaction [10]. In addition, recognition in the form of performance-based allowance establishes an equivalent of values that develop into high motivation [11]. And recognition contributes employee motivation by informal and formal contribution validation [12]. To add, job enrichment by adding autonomy to the job, which challenges individuals to skill improvement, enhances job satisfaction [13]. Jobs satisfaction is facilitated by employment opportunities such as career ladder and increase in responsibility [14]. The organizational identification strengthens the satisfaction level by encouraging some sense of purpose and belonging to a group [15].
2) H2: Job demand when paired with job support and control positively influence job satisfaction through moderate challenges that results to sense of accomplishment [16].
3) H3: Job satisfaction goes hand in hand with organizational commitment whereby an employee who is satisfied tends to over perform in the job than in the organization [17].
4) H4: Organizational commitment is positively influenced by psychological safety, when employees feel safe in speaking up and an environment fosters trust are loyal to the organization [18].
5) H5: Perceived organizational support likewise strengthens commitment, as employees who feel valued and supported show greater dedication and involvement [19].
6) H6: Personal resources such as job engagement and public service motivation are also critical drivers of commitment. When employees feel deeply engaged and believe their work contributes to societal good, they demonstrate stronger loyalty and resilience [20].
7) H7: Organizational commitment influences job productivity. An engaged worker who is immersed, dedicated, and satisfied with their role is closely linked to enhanced job performance [21]. Strong PSM fosters organizational commitment because employees internalize the value of contributing to society and view their roles as aligned with a larger mission [20].

2.3 Participants

This research applied a quantitative, cross-sectional design to assess job satisfaction and productivity among Philippine government workers. Data were collected via a structured online survey conducted using Google Forms. In line with [22], purposive sampling was used to recruit respondents aged 18 and above with government work experience, ensuring relevance to the study objectives. The survey link was shared through social media networks such as Viber. Instagram, and Facebook, and participants provided informed written consent before taking part in the study. Of the 268 individuals who completed the survey, only 253 responses were retained for analysis, excluding incomplete or non-government entries, as shown in the following Table 1.

Table 1: Sociodemographic profile.

Characteristics	Category	n	%
Gender	Male	96	37.9
	Female	157	62.1
Age	18 to 24 years old	37	14.6
	25 to 34 years old	115	45.5
	35 to 44 years old	55	21.7
	45 to 54 years old	30	11.9
	55 to 64 years old	16	6.3
	> 64 years old	0	0
Job Status	Permanent	164	64.8
	Casual	19	7.5
	Contract of Service	53	21.0
	Job Order	17	6.7
Work Experience	< 1 year	40	15.8
	1 to 3 years	50	19.8
	4 to 6 years	40	15.8
	7 to 9 years	37	14.6
	> 9 years	86	34.0

2.4 Measurements

In this study, the questionnaire used as indicated in the supplementary material was adapted from different studies. It consisted of 65 items distributed across 14 latent variables: job demand, psychological safety, perceived organizational support, rewards/compensation, job engagement, job enrichment, job opportunity, job rotation, recognition, organizational identification, job satisfaction, job productivity, organizational commitment, and public service motivation. A 5-point Likert scale was employed to assess each construct on a scale from 1 (strongly disagree) to 5 (strongly agree), designed to capture the level of agreement with statements reflecting various job-related and organizational perceptions.

2.5 Structural Equation Modeling

The structural equation modeling (SEM) was used in this study to analyze the causal relationships among variables affecting job productivity and satisfaction in the Philippine government, a method well-suited for examining human and organizational behavior. The use of partial least squares structural equation modeling (PLS-SEM) for exploratory models with multiple constructs and to handle smaller sample sizes was due to its suitability [23]. This approach also accounts for measurement error and can test both the structural and measurement models simultaneously. SEM has been widely applied in government research; for example, [24] used it to examine local employees' technology adoption, highlighting performance expectancy, social influence, and facilitating conditions as key predictors. Drawing from these precedents, the present study utilized SmartPLS v4.0 to evaluate the proposed extended PSM framework and examine the strength of causal relationships influencing job satisfaction and productivity among Filipino government workers.

3 RESULTS

3.1 Results of Initial SEM

Figure 2 illustrates the initial SEM, showing the influencing factors of Filipino public servants' job satisfaction. The model comprises 14 latent variables and 65 indicators. Following established guidelines [23], [25], [26], factor loadings below 0.70 were considered weak and excluded to ensure reliable measurement of latent constructs. Similarly, p-values greater than 0.05 were deemed statistically insignificant relationships [25] and were removed to enhance model fit. These insignificant paths are depicted as dashed lines in the model, indicating weak or non-significant relationships that did not meet the threshold for inclusion in the final analysis.

Table 2 shows the results from both the initial and final SEM models and responses by descriptive statistics. All measured items demonstrated factor loadings above the accepted threshold of 0.70, confirming satisfactory indicator reliability in accordance with [23]. However, all final indicators under Psychological Safety (PS), as well as the POS1 item under Perceived Organizational Support (POS), were excluded from the model due to their insignificant factor loadings, as shown in Table 3.

Using the heterotrait–monotrait ratio (HTMT) the measurement model and variable correlations were evaluated to establish discriminant validity alongside the Fornell–Larcker criterion (FLC) [27]. According to the FLC, it is acceptable when diagonal values exceed the corresponding vertical and horizontal values [25]. Further states that when HTMT values are below 0.85, discriminant validity is established [28]. In this study, demonstrating adequate reliability and discriminant validity, all HTMT and FLC values passed the established thresholds.

Model fit was assessed to validate the proposed model. All parameter estimates met or exceeded their respective thresholds, confirming the model's suitability. The SRMR value was 0.064, below the 0.08 cutoff, the Chi-Squared to degrees of freedom ratio was 3.528, within the acceptable limit of less than 5.00, and the NFI was 0.906, exceeding the 0.90 benchmark, as shown in Table 4.

4 DISCUSSIONS

Results showed a positive significant relationship between job resources and JS ($\beta = 0.685$, $p < 0.001$). This suggests employee satisfaction stems from multiple interrelated resources rather than a single factor. Among job resources, RC was critical. Employees satisfied with pay equity, benefits, and performance-based rewards reported higher satisfaction [32]. RE, including praise and awards, also enhanced satisfaction by making employees feel valued [33]. JO, such as training and clear progression, were important for long-term satisfaction [34]. JEN, involving autonomy and meaningful work, positively influenced satisfaction [35]. JR, providing exposure to different roles, reduced monotony and increased engagement [36]. OI was a strong predictor of satisfaction, reflecting employees' pride and loyalty to their organization [37]. Overall, these results confirm that job satisfaction arises from a combination of compensation, recognition, growth opportunities, enriched roles, job variety, and organizational pride.

And between OC and JP ($\beta = 0.631$, $p < 0.001$), a positive significant relationship was found. This aligns with, showing that committed employees tend to align with organizational goals, put in extra effort, and feel a strong sense of belonging which leads to higher productivity [38]. This study extends those findings to the Philippine public sector, supporting [39] who emphasized the importance of commitment for productivity across different economic contexts.

Personal resources also positively influenced OC ($\beta = 0.571$, $p < 0.001$). Employees who clearly understood their roles, embraced challenges, and aligned with organizational values demonstrated stronger commitment. This supports, who found that JE fosters belonging and loyalty, [40] and [41], who noted that PSM deepens attachment to the organization. Taken together, these results show that PSM and job engagement foster organizational commitment by enhancing satisfaction and sustaining long-term dedication.

JD showed a positive significant relationship effect on JS ($\beta = 0.259$, $p < 0.001$). Respondents reported higher satisfaction with reasonable workloads, supportive environments, helpful supervisors, and collaborative teams. This supports, who found balanced demands and strong social support reduce strain and boost satisfaction [42].

JS also positively influenced OC ($\beta = 0.243$, $p < 0.001$). Employees satisfied with compensation, benefits, leadership, career development, and recognition showed stronger commitment. This

echoes, who found that in Southeast Asian public service, satisfaction and commitment reinforce each other. Job satisfaction fosters loyalty and alignment with organizational goals [43].

POS positively affected OC ($\beta = 0.192$, $p = 0.001$). Employees who felt supported by supervisors and their organization, including development opportunities and work resources, showed stronger commitment [44]. Also found that perceived support reduces stress and fosters attachment by improving emotional well-being and work-life balance.

Lastly, interestingly, no significant effect between PS and JS ($\beta = -0.025$, $p = 0.692$). Despite respondents feeling their ideas were valued and supported, this did not translate into increased satisfaction. Unlike [45] findings in individualistic cultures where open communication drives satisfaction, psychological safety in the Philippine public sector may be less distinct, as collectivism and group harmony already provide baseline security.

4.1 Theoretical Implications

This study contributes theoretically by offering a holistic framework linking job satisfaction, job productivity, and organizational commitment in the public sector, which is an area often overlooked in prior research. It highlights how job resources, personal resources, job demand, and perceived organizational support interact to shape employee outcomes. By identifying key drivers of satisfaction and commitment, the model informs strategies for improving public sector performance. The framework not only deepens understanding of employee behavior in government settings but also offers a basis for future studies across other sectors and organizational contexts. Furthermore, in the context of the Philippines, the PLS-SEM utilization provides a deeper causal relationship in the public sector and introduces new local research, as shown in Figure 3.

4.2 Sustainable Managerial Implications

The findings offer critical implications for enhancing job satisfaction, productivity, and commitment in the public sector. Since satisfaction is shaped by resources such as compensation, recognition, career development, and meaningful work, agencies should prioritize equitable pay, growth opportunities, and role enrichment. The results also emphasize the role of perceived organizational support, job engagement, and public service motivation in strengthening commitment, underscoring the need for supervisors to foster inclusive, supportive, and purpose-driven environments. With this, it aligns with United Nations SDG 8, which focuses on decent work and economic growth, in the context of the Philippines. Integrating these drivers into the workplace impacts job satisfaction, which translates in excellent public service through a transparent leadership with shared cultural values.

4.3 Limitations and Future Works

Although this study explores government job satisfaction and offers new insights, some limitations are noted. It could negatively affect generalizability because the study that focuses on Filipino public servant it is proposed represent cross-sectoral or country comparisons. And also, use a data which is self-supported may introduce potential bias, in which future studies could incorporate a more comprehensive view thought observational data and interviews alike. And while this study utilized PLS-SEM, it is noted that other areas for public sector contexts like digital transformation offer an evolving area to explore.

5 CONCLUSIONS

This study examined the relationships among job demands, job resources, job satisfaction, organizational commitment, and job productivity within the public sector using the Job Demands–Resources (JD-R) framework.

The findings confirm that job demands and job resources play a significant role in shaping job satisfaction, while job resources also directly contribute to organizational commitment. Organizational commitment was found to mediate the relationship between job satisfaction and job productivity, highlighting its central role in translating employee attitudes into improved performance outcomes.

In contrast, psychological safety and public service motivation did not demonstrate significant effects in the final model, suggesting that structural and organizational factors may outweigh individual motivational constructs in this context.

These results contribute to the JD-R literature by providing empirical evidence from the public sector, emphasizing the importance of resource-based management strategies in enhancing employee performance. The study also extends existing research by clarifying the mediating role of

organizational commitment in linking satisfaction to productivity.

From a practical perspective, public sector organizations should prioritize strengthening job resources, including role clarity, engagement, and organizational support, to improve employee satisfaction and commitment. Such strategies can lead to more effective and sustainable improvements in job productivity.

Future research may explore longitudinal designs, cross-sector comparisons, and the integration of additional psychological and organizational variables to further refine the explanatory power of the model.
